LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

—
LECTURE I.

Introductory remarks on the claims of diseases of the chest to be separately considered—Importance of studying their physical as well as their general signs—Illustrations—Practical insufficiency of either class of signs separately—Advantages of studying both rationally—Analysis of the mechanism of respiration—Forces and mechanism concerned in dilating the chest, upwards, outwards, and downwards—Forces which diminish the cavity of the chest—Modifications.

GENTLEMEN,—A course of lectures devoted specially to the consideration of the viscera of the chest in their healthy and diseased state, may be open to the objection, that any partial study of a set of organs and their diseases tends to engross the mind with a disproportionate attention to these organs, to the neglect of general disorder of the system, and of affections of other important viscera. In answer to this objection, we might urge the great prevalence and fatality of thoracic diseases in this country; constituting nearly one *half* of the fatal cases, and perhaps quite one *half* of the slighter disorders; and we might strengthen

this argument by the fact, that many other diseases, both local and general, owe their serious or fatal character to secondary thoracic lesions. In fact, such is the immediate relation between the thoracic organs and life, that when diseases of other parts prove fatal, it is by arresting the functions of those organs, and when the process of this arrest is slow, morbid conditions are often produced in the lungs and heart, resembling those of their primary diseases, which speedily accelerate the fatal event by their superadded influence. It is thus found that in many of those who die of lesions of the brain, abdominal viscera, &c., especially those of a chronic character, the lungs are congested, and even hepatized, and effusions of serum and of lymph are found in the thoracic cavities.

But the great prevalence and fatality of thoracic diseases are not sufficient reasons for making the lungs and heart exclusive objects of study; the condition of extra-thoracic organs in these as well as in other disorders requires notice; and it will be a leading aim of the following lectures to direct attention continually to the general states of the system, as well as to the local disorder, and to show how important it is for the practitioner to instruct and guide himself by all the symptoms, general and local, vital and physical, in combination. I would, therefore, rather give another character of thoracic diseases, as a sufficient reason for treating of them separately. They are, in the present state of our knowledge, more than any other internal diseases, susceptible of clear and conclusive illustration; and this for two reasons:—First, because the structure and functions of the organs within the chest are, for the most part, simple and intelligible; secondly, because these organs, in the performance of their functions, have certain mechanical and physical relations, which may bring their conditions, healthy and morbid, under the more or less immediate cognizance of our external senses; so that

our study of the most serious internal affections may be approximated to that of simple external disease.

Studied merely through their general or animal signs, thoracic diseases are often as equivocal in their character and insidious in their progress, as they are serious in their tendency. Thus, *pain* is often absent in affections of the worst character, whilst it may be acute in trivial complaints. *Cough* depends on an undue irritation, direct or by sympathy, of the lining membrane of the air-tubes, a part only of the respiratory machine, and is by no means proportioned to, or determined by, the extent of the thoracic disease. *Dyspnoea* also depends on the sensibility of the nerves with regard to the change of the blood which should take place in the lungs, which sensibility we know to be influenced by a variety of causes foreign to the lungs themselves. The *pulse*, that "*res fallacissima*," is often not proportionately influenced by a visceral lesion, or when it is so, does not indicate the seat or extent of that lesion. So also *fever* is an affection of the whole system, and is neither a measure nor a constant concomitant of the maladies of individual organs. Thus we may have inflammation of the lungs, nay, even of the pleura, without pain, without dyspnoea, with little or no cough, without any constant character of pulse, or degree of fever. We may have cough, severe pain of the chest, dyspnoea, strong and quick pulse, and febrile disturbance, without inflammation of the lungs.

I will give you an example, which is not a very rare one:—An intimate friend of mine, a physician in the country, who was distinguished no less for professional abilities, than for a highly conscientious candour, was called to see a gentleman of middle age, who had long been suffering from dyspepsia, and who appeared to my friend to have one of the attacks of his usual complaint. There was no other pain than what he had been often accustomed to in his common ailment; he felt no dyspnoea, but only temporary oppression, as often before, from flatus; he had no cough; his pulse did not exceed 80; and there were nausea, and a feeling of general uneasiness, but no more fever than what frequently accompanies what is called a bilious attack. Such the complaint was considered to be, and as such it was treated. After several days of no remarkable change in the symptoms, the physician was suddenly called to the patient, whom he was shocked to find pale, cadaverous, bathed in a cold sweat, with an intermitting, thready pulse, and obviously dying. The change, or *sinking*, came on only six or seven hours before death; and yet, on inspection, almost the

whole of one lung was found in an advanced stage of hepatization; a sufficient proof that extensive inflammation must have been carried on for several days, although it gave no indication of its presence by general signs.

I will give you an example of a still commoner case, in which, if the general signs were less negative, they were still insufficient to attract the attention of the medical attendant. A practitioner asked me to see a patient, whom he had been treating for a *liver affection*. It was a labouring man, and he complained of great weakness, with some pain low down on the right side, which was full and tender in the region of the liver. The skin was slightly jaundiced, and he had profuse perspiration every night. The complaint began gradually, and obliged him to leave off work, he said, through weakness, which was increasing in spite of the tonic remedies which he then used. Although I was fresh from Paris, and the wards of Laennec, I was almost ready to fall into the opinion of the surgeon; but finding, on more minute inquiry, that there was a slight cough, I began to examine the chest. One tap of my fingers was enough to reveal where the chief disease lay. One side of the chest, the right, was full of water, the effusion consequent on a latent pleurisy. This extensive local disease, although not evident by distinctive general signs, had already begun to oppress the functions and reduce the strength, and if still neglected, it would most probably soon have taken on a chronic form, accompanied by changes of structure, over which medicine exerts very little control, and if then discovered, the body would have been wasted and worn down before any beneficial influence could have reached the real seat of the lesion. As it was, a series of large blisters to that side, mercurial diuretics, followed by tonics and similar appropriate treatment, soon effected a cure.

Such cases as those now mentioned are by no means very rare; many examples have happened within my own observation, where a latent pneumonia or pleurisy has been revealed only by the scalpel after death. In many instances, too, the same lesions have been discovered during life as unexpectedly by auscultation; and if the discovery has not been always followed by a successful treatment, it has at least saved the practitioner from errors which would have degraded his skill in the eyes of others—errors with which his conscience would have been often haunted in hours of despondency and self-distrust. But in many cases, such a discovery of the true nature of the disease has prompted a line of treatment which has proved palpably successful; and

the certainty of the information thus obtained gives to the practice a decision and an energy that a conscientious man can never bring to bear in cases of perplexity and doubt.

It has occurred to me in a good many instances, to see patients supposed to labour under complaints called bilious, dyspeptic, nervous, or designated by the more convenient term general debility; and these patients do truly exhibit many symptoms of biliousness or dyspepsia, nervous irritability or weakness: but instead of being benefited by the remedies usually resorted to in such affections, calomel and black dose upset them, peptic remedies do them no good, active exercise aggravates all their complaints; tonics and stimulants are equally prejudicial; and the patients have gone from doctor to doctor, getting nothing better than temporary relief, and oftentimes getting something worse. In these cases, the liver, the stomach, the nervous system, the general strength, have truly suffered, but they have suffered secondarily. A disease, either functional or structural, of another organ, has been the true *fons et origo mali*; and that organ is the heart. This, by failing in its important duty of carrying on the circulation, that spring of all functions, whether its propulsive force be insufficient, or whether its valvular apparatus admit regurgitation, involves other organs in disorder; viscera are congested, secretions depraved, sensibility deranged, functions disturbed, muscular power impaired; and all these effects may be obvious and distressing, whilst the original cause is either imperceptible or eclipsed amid the crowd of mischief that it has raised. Now I do not mean to assert that in all such cases physical signs will discover the cause, or by discovering it will enable us to remove it; but I can state with some confidence that they will often discover it, and they will then generally enable us to direct our practice more successfully and more safely than we could do without them.

I might easily multiply illustrations, but let one more suffice. The late epidemic, so injudiciously designated by the single name influenza, in many instances comprehended the most serious inflammations of the thoracic viscera, which were masked by the general symptoms, and were to be detected among the catarrhal and bilious affections common to the disease, only by means of the physical signs.

For the sake of my junior hearers, it may be well to explain here that *physical signs* are those which the diseased part can impress on our external senses, directly or through some physical medium. Thus the ocular examination of an external dis-

ease—the feeling of a tumor within the reach of the fingers—the listening to sounds depending on the form, position, or density of internal parts—all furnish us with *physical signs*; which, as they are produced by invariable and intelligible physical laws, are free from the fallacies of general symptoms, which depend on the varying and more mysterious properties of animal life—such as sensation, irritability, and sympathy.

While I would thus maintain the importance of attention to physical signs, I am very far from wishing to supersede the study of constitutional conditions. Let physical signs be taken according to their worth. They inform us of local lesions of structure or of function; but they do not tell us of the relation of those lesions to the body at large, or to other parts of the body: diseased function and condition may be in other parts also; and whether as cause or as effect of the local physical lesion, they are as much as this to be considered in estimating the condition of the patient and in determining the method of treatment. Thus, in the typhoid form of inflammation of the lung, the physical signs scarcely indicate any difference in the condition of the lung from that in common inflammation; but the general signs—the weak thready pulse, the clammy surface, the brown tongue, the oppressed senses, and the extreme general prostration—these show a state of the body of far more importance than the local disease as declared by the physical signs, and in a more imperative degree requiring its treatment.

Again, some morbid conditions which give physical signs are not enough characterized by these alone; but when their constitutional symptoms are also considered, the physical signs then appear in their true light. Thus œdema of the lungs has the same physical signs as the first stage of pneumonia; but the absence of fever, of pain, and the presence of anasarca in other parts, will generally supply what is wanting to distinguish the former from the latter affection.

Further, the positive indications of physical signs, although in themselves accurately detecting disease of an organ, will often be insufficient alone to guide the treatment. Thus organic valvular disease of the heart I may detect by physical signs alone, and I may through them specify with exactitude its nature and extent, but the course of treatment will depend on the general state, the bodily strength, the vascular fulness, the degree of nervous excitability, and the condition of other functions; whilst, at the same time, the organic disease of the heart which the physical signs alone may have discovered, must

also be held in view as a permanent influence to be duly respected in the whole course of the treatment.

Even thus limited, the importance of physical signs will still appear to predominate; for if positive in character, they tell us far more of the real nature and amount of the organic disease than any assemblage of general symptoms; they are more truly the representative of the lesions themselves; in fact they are absolutely part and parcel of these lesions. To illustrate this, a patient with peripneumonia may have severe pain, little pain, or no pain at all—much or little cough; he may be oppressed by dyspnoea, or not be sensible of it at all; his pulse may be soft or hard, and variously quick; there may be thirst, anorexia, heat of skin, and other indications of fever, or they may be scarcely present; and these several symptoms are so far from marking the disease, or bearing proportion to its extent, that they may all exist in a high degree without pneumonia, and pneumonia may be present without enough of these symptoms to attract attention. But pneumonia cannot exist without changing the physical condition of the lung—the physical condition of the lung cannot be changed without an alteration of its physical properties—and these physical properties may, in the majority of cases, be made more or less evident to our senses. We study these physical properties by the senses that can reach them; we watch and feel the motions of the respiratory machine; we listen to the sounds which they produce, and to the sounds which we can excite in them. When we detect in these movements and sounds those modifications that experience and reason have shewn to depend on inflammation and condensation of the pulmonary tissue, we know, almost with the certainty of seeing, that pneumonia is present; and the extent of the signs thus shewn, will be a pretty accurate measure of the extent of the lesion. On the other hand, although there be many general signs which seem to denote the existence of peripneumony, if, on careful examination, none of the physical signs are found, we may well distrust the affirmative general symptoms with regard to the diagnosis, although, if positive, they are not to be disregarded in the general treatment. Both sets of signs have their value; and it will be my especial object, in the course of these lectures, to point out modes of appreciating each in the study and treatment of the diseases—to shew as much as possible what they are severally worth, by examining them more fundamentally than has generally been done—and, whilst we pay due respect to the records of experience, in whatever

shape they may come before us, to make them still more profitable and instructive by careful analysis and moderate generalization.

Now, then, what must be our course to attain this knowledge that shall be at once rational and available? We must imitate the practical philosopher, who wishes to use, repair, or improve a complicated piece of machinery: he studies the springs, the wheels, and all the parts of his machine, their uses and relations to each other, and the laws according to which they act severally and in unison. We must likewise study our machine; we must duly consider its construction—the form, position, and connexion of its several parts; their relations to physical laws, and the combinations of these relations in the rest and in the working of the whole. But in doing this, we shall soon discover that the object of our study is more than a mere machine; we shall find springs in it that are not elastic—chains that are not mechanical—phenomena present themselves which imply properties other than those of mere matter. The laws which regulate these properties beyond those of mere physics, claim also to be carefully studied. We have the *vital* properties, sensibility, irritability, contractility, added to the mechanism—we have a vital chemistry pervading the materials. Besides the chest, which is mechanically enlarged and diminished, and the bag of the lungs and their tubes, which are in like manner expanded and compressed, and the heart and its hydraulic pipes, through which a liquid is propelled, there are in these several parts also the properties of feeling and sympathy, of irritability and the power of secretion; and these not only bind together, in new and complicated relations, the various parts and organs of the chest, but they connect these severally no less with the other organs and members of the body; and the affections resulting from these varied relations, must have their proper share of our attention.

Thus, then, again arises the division of signs into physical and general; the one class confined to the organs and their physical properties, as manifested in these organs; of the other, although a few may be located in the parts, many, through the various vital properties that link its parts together, are expanded over the whole frame; and thus becomes further evident the necessity of duly appreciating the study of both classes of phenomena in the investigation and treatment of disease.

With these objects in view, we proceed, then, to examine briefly the general structure of the chest and its organs, with such a concise account of their functions as

may be necessary to prepare us more fully to understand their diseases. We shall then be able to study the relations of these organs to physical laws, by which their condition may be examined, and the physical signs of health or of disease may be detected. As we enter this subject, it may be necessary to illustrate familiarly a few points of a branch of physical science, acoustics, which is by no means generally understood, and which is yet quite necessary to the right comprehension and appreciation of the phenomena of auscultation.

Now you see that we have chalked out for ourselves no trifling undertaking; and for me to succeed in it, and for you to profit by it, continued attention on your part will be as necessary as in any other study which is progressive and systematic. I have been asked by several, "When do you begin your lectures on the stethoscope? we want to know how to use the stethoscope." Why, gentlemen, the stethoscope stands in the same relation to this course of lectures, as that in which the telescope does to astronomy. To know how to use the stethoscope is as soon learnt as to know how to look through the telescope; but unless your only end be curiosity or wonder, you will use these instruments to no purpose, without studying, and understanding also, the phenomena which they reveal, and the laws which govern these phenomena.

It is only by this fundamental mode of study that we can attain any thing like a complete or really safe knowledge of the physical signs of disease. To burthen the memory with a long and unintelligible list of dogmas, that such and such phenomena indicate the presence of such and such lesions, without endeavouring to instruct the understanding as to the connexion between them, will be as useless and fallacious in practice, as it is unworthy of a branch of science.

The chief advantage of physical signs is in their being *intelligible* and *explicable*; that is, referable to known laws or classes of phenomena. To understand these laws and their fulfilment in the various phenomena of matter, is the object of natural philosophy; and if we expect physical signs to aid us in the study of disease, we must examine them by those modes in which simpler nature and her signs alone become intelligible, in their relation to fixed principles and simple laws. The Hippocratic physician, who studies only general signs, must often content himself with registering them in his memory, because many of these signs depend on vital properties which are little known, and occur according to laws which have been but imperfectly developed; but to extend

this uncertainty and imperfection to *physical signs*, the phenomena of *known laws*, the results of well-defined properties, is to carry into physics the doubt and mystery of medicine, and to deprive pathology of the only advantages of certainty and simplicity which physical science is capable of bringing to it. Vital properties, moreover, also have their laws; and the more we can keep these in view in the study of general signs, the more useful and instructive will be the information which we derive from them.

We have not time to enter into a minute detail of the anatomy of the chest, nor, indeed, is it necessary. I presume that you are already familiar with its structure, and I have now only to advert to the chief constituents of the machinery of respiration, and the mode in which these work.

The machine of respiration was compared by Mayow to a bag within a bellows, the bag alone communicating with the external air, and becoming full or empty as the bellows expands or closes. The comparison must be admitted as only a rough one, for there are many points of material difference. The alternate enlargement and diminution of the chest are certainly the chief movements in respiration; and in proportion as these are complete, and those of the lungs harmonize with them, the mechanical part of respiration will be effectually performed.

Now the chest is, as you know, enlarged essentially by muscular action, but its diminution is chiefly effected by the elasticity and weight of the parts, occasioning their collapse or subsidence from that condition to which the muscular action had brought them. Thus in ordinary breathing, inspiration is active, and expiration in a great measure passive, and the period of action is alternated with a much longer period of rest. As these motions of the respiratory machine constitute an element important in the production of many signs, we may well bestow a few more minutes upon them, especially as they do not seem to be fully understood by some modern pathologists.

Before we describe the means by which these motions are effected, let us illustrate their nature by those of the organs on which they operate. Here are healthy lungs, and observe the character of their expansion when I inflate them: their summits rise, their middle portions expand, and their bases and margins descend and spread. Their motion is, therefore, peripheral, or radiating from a centre: now where is this centre or most fixed point? Why, not at their summits,

as some modern writers have erroneously supposed, but at their roots, where they grow, as it were, from the bifurcated trunk of the trachea, which, where it again divides, becomes in a measure fixed by its attachment to the great blood-vessels and the spine. So also shall we find the enlargement of the chest to be peripheral nearly in all directions, the spine being the fixed centre. Its chief increase is indeed downwards and around its lower portions; but if we watch the upper parts with relation to the spine, we can plainly see them also rise and expand considerably. This general enlargement of the chest may be analysed into its enlargement *downwards, upwards, and outwards.*

The enlargement of the chest *downwards* is, as you know, effected by the action of the diaphragm, which in its passive state projects in a very convex form upwards into the chest, but when acting, its muscular margins and pillars draw its tendinous centre downwards towards their attachments to the lower margins of the ribs and sternum, and the upper lumbar vertebrae. In the same contraction the muscular portions of the diaphragm being straightened towards the centre, touch the ribs at fewer points, and form angular spaces, in which the thin marginal lobes of the lungs become expanded downwards. Now as this downward action of the diaphragm cannot take place without pressing on the contents of the abdomen, it causes an outward movement of these contents, and the swelling of the abdomen at each inspiration therefore becomes an index of this action.

The enlargement of the chest *upwards*, by which the apices of the lungs are expanded, is effected by the drawing upwards of the upper ribs, sternum, clavicles, and scapulae, by the sterno-mastoid, scaleni, and other muscles, which connect this upper frame work of the chest directly or indirectly with the upper end of the spinal column. This motion, although not great in ordinary respiration, is yet in proportion to the extent of the upper lobes of the lungs. It has been overlooked by many physiologists, but it is highly important as a source of diagnosis; and you may perceive and measure it if you keep steady the spinal column by standing with the back against a pole, or the edge of a door, or the corner of a wall; you will then see that the upper ribs rise to the amount of half an inch or more in each inspiration; and so far from being, as Haller and others maintained, almost fixed, they are, in proportion to their length, actually more moveable than the lower ribs. If you examine their attachments to the vertebrae, you will there perceive that the upper ribs admit of more

motion than the lower. Magendie, I believe, first pointed out this important part of the movements of respiration, and you now see how it accords with the expansion of the lung which I have just exhibited to you.

The *outward* enlargement of the chest is mainly effected by the contraction of the intercostal muscles. I dare say that you may have heard or read of the long discussions which were formerly excited by this apparent paradox, that of a cavity *being enlarged by the contraction of its walls.* It is, indeed, a mechanical process hard to be described, and yet how plain and simple it is on inspection! See how these ribs, especially the lower, in their collapsed state, are convex downwards in the portions anterior to their centres. Well, now, these are their most moveable portions, and if they are drawn upwards, the ends being comparatively fixed, you see that their downward convexity is diminished, and their outward convexity or inward concavity is enlarged, and thus the horizontal diameter of the chest is increased.

But observe, for this effect it is necessary that the ribs should be drawn *upwards*; and what is it that makes the contraction of the intercostal muscles draw the ribs upwards rather than downwards? Haller and others say it is because the upper ribs are fixed, and cannot be drawn downwards; but we have just seen that they are not fixed: the fact is that they are drawn upwards themselves by muscular action, and this upward traction is communicated and increased to the ribs below by the contraction of their respective intercostal muscles. If instead of drawing up, or fixing the upper ribs, you draw down, or fix the lower ones by the abdominal muscles, then the intercostal muscles become means of diminishing the diameter of the chest by drawing the ribs downwards; and they actually do contribute to this end in forcible acts of expiration. Now here is a case illustrating the necessity of learning the mechanism of the chest rationally, and not merely by rote. You see that both sets of intercostal muscles, external and internal, must tend to elevate the ribs as long as the upper ribs are either fixed or drawn upwards; but when the lower ones are fixed, the contraction of the intercostals must approach them to this lower fixed point.

Well, now, let us go back a moment, and apply the same question to the diaphragm, whose *ordinary* action we found to be to enlarge the chest downwards by the drawing down of its central convexity. This supposes its tendinous centre to be the most moveable attachment of the muscular portion of the diaphragm, that to

the lower margin of the ribs and sternum being more fixed. But the centre of the diaphragm is sometimes more or less fixed, and prevented from descending, by tumors or excessive tenderness of some of the abdominal viscera below it. How will its muscular margin then act? Why, it will draw upwards its lower attachment with the ribs and sternum, and thus increase the capacity of the chest by raising it from the fixed convexity of the diaphragm. When, therefore, you see a patient breathing merely by the heaving of his chest, you are not to suppose that the diaphragm is inactive, for it may thus contribute to inspiration that is wholly *thoracic*. This upward action of the diaphragm is not considerable in common cases; but it must always be something—that something being the amount of resistance offered to the descent of the diaphragm by the contents and walls of the abdomen.

There is another particular in the ordinary action of the diaphragm which is worthy of your notice, because it may prove a source of physical signs. You see, by these diagrams, that considerable parts of the upper abdominal viscera, the liver, the stomach, and the spleen, although below the diaphragm, yet are contained within the walls of the chest. Now the portions of these walls which contain them differ from those above the diaphragm, in being subjected to the ever-repeated outward pressure of these viscera, pushed by the descending diaphragm; and the result of this pressure is a permanent bulging or prominence in the lower part of the chest, and a slight furrow or depression above it. This depression generally marks the situation where the lung begins, and where the abdominal viscera cease to be in contact with the walls, although they generally rise above it towards the centre of the chest. The existence of this furrow, and its use as a sign of limits, were first pointed out to me by my friend Dr. Edwin Harrison, and I think I may explain its production by the outward pressure of the sub-diaphragmatic viscera. The position of this furrow varies in different subjects, but may generally be traced from the lower end of the sternum running horizontally around the chest, about, but not parallel with, the seventh and eighth ribs at the sides.

The effect of the reiterated outward pressure of the subdiaphragmatic viscera is remarkably seen in the eversion of the lower ribs and sternum in ricketty children, the bones and cartilages being permanently bent by it. If the belly in these cases be also tumid, the upward action of the diaphragm will draw the sternum forwards and upwards, forming what is called a *chicken-breast*.

We need not dwell long on the ordinary means by which the capacity of the chest is diminished. When the diaphragm ceases to contract, the weight of the viscera and walls of the abdomen force back the diaphragm to its wonted vaulted projection into the thorax: the same weight to the lower ribs, together with the elastic torsion of their cartilages and ligaments, make the ribs collapse on the relaxation of the intercostals and the muscles which raise the upper part of the chest. The merely mechanical constitution of the chest is in favour of its diminution, and so is that of the lungs, which we shall notice by and by; but expiration may be most powerfully assisted and increased by a great many muscles, especially the abdominal muscles, and all those connecting any of the ribs with a part of the spine *below* the attachments of these ribs.

So, likewise, forcible inspirations are assisted by the action of all those muscles connecting any of the ribs with any part of the spine *above* the attachments of these ribs.

A BRIEF ACCOUNT
OF
IRREGULARITIES IN THE HUMAN
ARTERIAL SYSTEM,
OBSERVED DURING THE SESSION OF 1836-37.

To the Editor of the Medical Gazette.

SIR,

You will oblige me by inserting the accompanying paper in your widely circulated journal.

Your obedient servant,

HAMILTON LABATT,
Demonstrator of Anatomy, Royal Coll.
of Surgeons, Ireland.

Dublin, Sept. 7, 1837.

On taking a view of the different accounts which have been given of the varieties in the arteries of the human body, it is somewhat remarkable to observe the very few instances in which the state of the arterial system on both sides of the body has been specified. If, for instance, we examine the splendid work by Tiedemann on this subject, we find 19 cases of irregularities in the arteries of the upper extremity delineated, 14 of which were on the right side, and but 5 on the left; no mention, with the exception of two or three examples, is made of the opposite extremities. Now, inasmuch as the arterial distribu-

tion of one side is by no means an index of that of the opposite one, so we must immediately see how desirable it would have been that the state of both had been more frequently alluded to. Thus we should have been enabled to draw some average calculations which might prove useful in a practical as well as a physiological point of view.

Arterial irregularities are generally symmetrical, but we may have the arteries of one side perfectly normal, while the corresponding vessels of the opposite side are abnormal; or lastly, irregular distributions may exist on both sides, yet totally different from each other. A remarkable instance of the last occurred to me during the season, and I procured a drawing of it, in consequence of a peculiar disposition of the thyroid arteries, which, as far as I know, has been hitherto unnoticed. On the *left* side I could not discover a vestige of those vessels; on the right, the superior came off from the carotid at its bifurcation, and the inferior from the first stage of the subclavian; no thyroid axis existing. Next with respect to the mammary arteries, the right proceeded from the subclavian in its third stage, and passing inwards, under the interior scalenus, sought its usual destination. The left mammary arose from the second stage of the subclavian. Lastly, in the same case, the left vertebral passed from the arch of the aorta between the left subclavian and carotid. This irregularity of the left vertebral is by no means uncommon in the human subject. According to Tiedemann it is normal in the *Phoca vitulina*.

Before I pass on to another division I may mention a second remarkable deviation in the thyroids. It was an instance of the *inferior* thyroid being deficient on the left side, and the *superior* on the right. Meekel and Green have recorded examples where there was no inferior thyroid, but I do not find any of their cases corresponding with the above.

With the exception of the case already mentioned, of the vertebral proceeding from the arch of the aorta, I have had an opportunity of noticing but two other instances of irregularities in the vessels proceeding from that great trunk. In both, the left carotid arose from the innominate, and passing across the trachea ascended, as usual, on the left side of that tube. In one of them, the artery

was given off immediately at the origin of the parent trunk, and the unusual size of the vessels in this case particularly attracted me. The diameter of the aorta, found by taking $\frac{1}{3}$ of the circumference, exceeded $1\frac{1}{2}$ inch, and the innominate nearly equalled a regular aorta. The subject was an adult male, and the vascular system throughout the body was developed in an equally remarkable degree. The preparation is preserved in the College Museum, and the drawing in my possession represents the above measurements.

A similar example occurred here in the course of last season, and was brought before the Chirurgical Society by Mr. Williams, who presented the preparation to the School Museum. In his case, however, the left carotid was more connected with the front of the trachea *above* the sternum, so as to interfere with the line of incision practised in tracheotomy. In neither of my cases was it so disposed, being, in both, completely *substernal* in the whole of its transverse course, and not liable to interfere with the success of such an operation as long as the mesial line above the sternum was observed. In one of them the left vena innominate might have been endangered, as it was situated higher than usual. If we consider the above irregularity in another point of view, it will be interesting to remark that it represents the normal type in some animals, as the marmot, guinea-pig, &c.

Connected with the axillary artery, I met with an example nearly similar to one given by Tiedemann, of an irregular branch, in size equalling the ulnar, (analogous in many respects to the profunda femoris,) proceeding from that trunk at the lower border of the lesser pectoral, and, after giving off the subscapular and circumflex, passing between the roots of the median nerve, and running down the arm internal to the main trunk, to terminate in the anastomotic, after having given off the profunda. In this subject, the brachial plexus was quite posterior to the axillary artery.

High bifurcation of the *brachial* artery is of frequent occurrence: according to Cuvier it is normal in the kangaroo, and other marsupial animals; and Tiedemann has observed it in some of the quadrumana, as the *Lemur gracilis*. So frequently is it met with in the human subject, that Dr. Barelay says we can scarcely call it an anomaly. Four

cases, all differing from each other, were noted by me during the season, and I shall briefly describe them from the drawings which I took at the time.

In the first, the bifurcation was about two inches above the bend of the elbow. The ulnar artery, instead of pursuing its deep-seated course, as is usual in the high division, passed superficial to the pronators and flexors, covered only by the palmaris longus, fascia, &c.; and, instead of giving off the interosseal, the radial supplied that artery, which reminds us in some degree of the type in birds, where the radial, after supplying the muscles about the radius, is lost in the interosseal arteries. The second case was similar, except that the ulnar passed immediately under the fascia over all the muscles. In the third, the bifurcation took place immediately after the origin of the superior profunda, and in this example the brachial plexus was posterior to the axillary artery*. The fourth and last case was the most remarkable, and is of rare occurrence. The brachial divided at its origin; the internal or ulnar branch, larger and deeper seated than the external or radial, after giving off the profunda and three small muscular arteries, communicated with the radial by means of a transverse branch, which crossed the tendon of the biceps. An inch and a half below this, the interosseal arteries proceeded separately from the ulnar; the lower one, the anterior interosseal, as large as the radial, gave off a median branch, which, piercing the median nerve, accompanied it down the fore-arm, and, becoming superficial towards the carpus, passed under the annular ligament, to terminate in two muscular branches for the thumb: no superficial palmar arch; digital arteries of index finger and external side of the middle finger supplied by the radial, as it was about to form the deep palmar arch: the other digitals proceeded from the ulnar. This irregularity, with some modifications, has been observed by Tiedemann, Meckel, and Green, and the last remarks that the transverse communication is only to be met with in the high, or axillary, bifurcation. The median branch sometimes comes from the transverse one, and forms the palmar arch with the ulnar†.

Before I leave the upper extremity I may mention a case where the superficial palmar arch was deficient, and the ulnar supplied all the digital arteries, except that of the external side of the index finger, which proceeded from the radial. This variety is by no means frequent; it assimilates the type in birds where there is no palmar arch, and the ulnar is the principal trunk for the wing. The arteries on the left side were regular.

With the exception of one example, I have not taken notes of any varieties in the abdominal arteries. They are of very frequent occurrence, but of no practical importance. In the case of which I have taken a drawing, a second hepatic artery proceeded from the aorta, about an inch below the celiac axis, and passed under the vena porta to reach the right extremity of the transverse fissure, where it supplied a cystic branch. The regular hepatic divided as usual. The above distribution is, I believe, rare.

I shall now describe two very unusual varieties in the obturatrix artery, connected with equally remarkable ones of the epigastric. In the first, of which I have preserved a drawing, the obturatrix arose from the external iliac, above Ponsart's ligament, and coasting along the anterior margin of the crural ring (in the centre of which it gave off at right angles considerably smaller vessel, which proved to be the epigastric,) descended into the pelvis to reach its destination. About a quarter of an inch before its exit from that cavity it gave off the dorsal artery of the penis, which, running along the side of the prostate gland, pierced the triangular ligament a little above the urethra, and sent off the artery of the crus. The pudic of this, the left, side terminated in the artery of the bulb. The vessels on the right side were perfectly regular. I need not here mention how formidable such a case would be for the lateral operation for stone, as also the danger of operating on such a patient for crural hernia.

The above is of exceeding rare occurrence; it is the first instance I have seen of it. I distinguish it particularly from examples of the obturatrix arising from the epigastric, which was to be seen frequently during the season in our dissecting rooms, and must be familiar to every anatomist.

In one of the many cases of the obturatrix proceeding from the epigastric

* This disposition of the nerves I have met with on three occasions during the season. In one, the arteries were regular.

† The above irregularities existed on both sides.

which came under my notice, I remarked a very peculiar course of the epigastric vein. This vessel, of considerable size, passing downwards and outwards at some distance internal to the artery of the same name, crossed the gland in the crural ring (dividing the opening as it were into two) to reach the internal side of the external iliac vein. If a crural hernia occurred in such a subject as this, and if the sac passed between the epigastric and external iliac veins, we should be in danger of dividing in our operation, not only the obturatrix artery, but also a vein rendered of peculiar importance by joining so large a vessel as the external iliac vein. I have preserved a drawing of this.

Besides these varieties I have seen one instance during the season of the epigastric and obturatrix arteries arising from the femoral about half an inch below Poupart's ligament, and it was remarkable that the former, instead of ascending directly from its origin, first formed that arch downwards which it usually does. The obturatrix passed upwards on the pectineus behind the gland in the crural ring, and descended into the pelvis. Meckel states this variety to be very rare, and Tiedemann has seen but two cases of the epigastric proceeding from the femoral.

Although the epigastric artery sometimes varies in its point of origin, I believe it is seldom found to deviate with respect to its relative anatomy. I have seen but one instance when it was not subjacent to the transversalis fascia in its course up the abdomen, and in that remarkable case, which occurred early in the season, it passed through a distinct opening in that fascia immediately after its origin from the iliac, and remained superficial to it in its course upwards and inwards*.

Irregularities of the femoral artery are fortunately of rare occurrence. In the 4th volume of the Dublin Hospital Reports a very interesting case of high division of the femoral and union within the tendinous canal, has been recorded by Dr. Houston, and the preparation may be seen in the College Museum. I have but two cases connected with this vessel to mention. Of the first I have made a preparation for the School Museum. It was an instance of an

unusual size, origin, and, I may add, distribution of the external circumflex, which arose from the femoral under cover of Poupart's ligament, about a quarter of an inch below the circumflexa ilii, and passed down external and parallel to the parent trunk for about four inches; it then bifurcated under the rectus muscle into muscular branches. The proper circumflex vessels came off at its centre. In such a case we would be very liable to mistake the circumflex for the femoral in cutting down for the latter, more especially as the former was quite as large as the profunda, which, it may be well to state, came off from the crural as usual.

In the second, the profunda arose from the femoral about an inch below Poupart's ligament, and ran external to it for about two inches. Besides this, five irregular branches of considerable size come off from the crural, almost equidistant from each other, before it reached its fibrous canal. Here two points occurred for consideration: first, the liability of taking the profunda for the femoral in the operation first alluded to; and secondly, even though we should secure the proper trunk, the danger of secondary hæmorrhage occurring *if the neighbourhood of a considerable branch to the point of ligature can really be the cause of such*. I put the point hypothetically, because I believe considerable doubt now exists on the subject; and I may adduce, as bearing on the question, a case in which the carotid was tied with perfect success by Professor Porter immediately at the starting off of the subclavian. It is most probable that an internal coagulum would not form in such a case, but we have no grounds for concluding that our success should be interfered with in consequence of its absence. It is true that operations have been said to have failed because of the neighbourhood of a large branch to the point of ligature, but when we come to consider the many causes of failure which may escape our notice, it is after all very difficult to settle on the true origin of the failure.

I shall conclude by describing a distribution of the parts in the popliteal space, such as I have not before met with: a very correct drawing of it, which is in my possession, (which I hope soon to place before the profession, with other sketches,) represents the gastrocnemius with three heads; the superadded one

* "L'artère (epigastrique) est constamment placée derrière le fascia transversalis."—*l'écuyer, Surg. Anat.*

arose from a distinct eminence on the posterior part of the femur, between the condyles, by a thick bundle of muscular fibres, and, passing downwards and inwards, distinct for about three inches, joined the internal head. Between these two heads, the artery, vein, and nerve, were closely impacted; the vein nearest the bone, and the artery lying on it covered by the nerve. This case needs no comment; the difficulty which would be experienced in securing the artery, if such was attempted, must be apparent.

With respect to the many varieties which we meet with in the human muscular system, it would be interesting to inquire, how far we find such adopted as normal in other animals.

A REPORT OF

THIRTY-FOUR CASES

OF

PUERPERAL CONVULSIONS.

BY ROBERT LEE, M.D., F.R.S.

Lecturer on Midwifery at St. George's Hospital,
and Physician to the British Lying-in Hospital.

CASE I. —, *æt.* 22; first pregnancy; ninth month; unmarried. Edinburgh, 1816.—Numerous violent fits of convulsion at short intervals, without a return of consciousness, for twelve hours. Orifice of uterus soft and dilatable; but no sign of labour. The pulse was rapid and feeble. The fits continuing, with coma, the child was turned without difficulty and delivered. Death in six hours. Blood-vessels of brain distended. No other morbid appearance observed.—V.S. ad 3l.; head shaved; cold lotion; calomel; enemata; artificial delivery.

CASE II. —, *æt.* 26; first pregnancy; ninth month. 12th July, 1823.—Fifty hours in labour. Head of child low in the pelvis. Vagina and perineum rigid; pulse full and strong; face flushed; occasional incoherence and slight convulsive tremors of the face and extremities. Venesection, followed by two severe fits of convulsion and insensibility. Unsuccessful attempts to deliver with the long forceps. Craniotomy. No fit after delivery. Consciousness soon returned. Uterine inflammation. V.S. 3xviii. Cathartics. Cured.

CASE III.—Mrs. L.—, *æt.* about 26. January 22, 1827. First pregnancy; seventh month.—Eight weeks before delivery suddenly seized with coma, from which she recovered after copious V.S., &c. Headache, giddiness, and partial loss of speech, but consciousness and memory have remained. Slight hemiplegia of the right side. Pulse 90. Went to the full period; labour natural. In a few hours, convulsions, coma, dilated pupils; retention of urine; and she died on the 29th. Upper surfaces of both hemispheres partially coated with a thick firm layer of lymph. Softening of the brain below. The veins distended with firm coagula. Ventricles filled with serum. The ventricles did not collapse after the fluid had flowed out. Copious V.S. and cupping, head shaved, cold lotions, and blisters; cathartics; low diet.

CASE IV. —, *æt.* 20; 1827. First pregnancy; seven and a half months; unmarried.—Had attacks of epilepsy for several years during early life. Headache, drowsiness, loss of memory; paralysis of right inferior extremity after a slight fit of convulsion and coma. Labour natural; child alive. No return of symptoms after delivery. V.S.; cupping; head shaved; cathartics; low diet. Cured.

CASE V. —, *æt.* 24, 21st June, 1828; third or fourth pregnancy; seven and a half months.—Subject to epilepsy in early life. After suffering for several days from an uneasy sensation of weight in the head and giddiness, was suddenly attacked with convulsions, of which she has had several fits, and has little or no consciousness in the short intervals. Os uteri closed. No symptom of labour. 2d June: no fit, but considerable stupor continues. Pulse 80; copious alvine evacuations. 24th: no return of convulsions; and she went to the full period, and was safely delivered of a living child. V.S. 3xx.; head shaved; lotions; enemata; cathartics; V.S. 3xii.; low diet. Cured.

CASE VI. —, *æt.* 18, 24th Jan., 1829; first pregnancy; 9th month.—Delivered at 11 A.M.; labour natural. The expulsion of the placenta was soon followed by a strong fit of convulsion. V.S. was immediately employed. At 4 P.M. frequent severe fits, without any intervals of consciousness; V.S. re-

peated. At 8 P.M. the fits and stupor continued, when forty drops of laudanum were prescribed in my absence.

25th.—Fits continue; twenty drops of laudanum, and sinapisms to the legs, were then ordered by her medical attendant.

26th.—Several fits of convulsion in the course of the night. Has taken sixty drops of laudanum at three doses, which appeared to calm the violent agitation after the paroxysms.

27th, 10 A.M.—Severe and frequent fits during the night; breathing stertorous; pulse rapid and feeble.

Died on the 28th.

I examined the brain, but except a slight turgescence of the blood vessels of the pia mater, no morbid appearance was observed.

V.S. \mathfrak{Lxxxv} .; V.S. \mathfrak{Lxxij} . Head shaved; enemata; calomel; ol. ricini; tinct. opii; sinapisms, &c.

CASE VII.—Mrs. —, æt. 24, first pregnancy; ninth month unmarried. 1828. A weak delicate woman; had several fits of convulsion in the first stage of labour, in consequence of which she was severely bruised in different parts of the body. She was completely insensible in the intervals. The pains ceased, and the os uteri being only partially dilated, and the head of the child being too high in the pelvis for the forceps, the delivery was completed by craniotomy. The fits soon after ceased. V.S. \mathfrak{Lxxxv} .; do. \mathfrak{Lxxij} . Cured.

CASE VIII.—Mrs. H., æt. 24, first pregnancy; ninth month. Sept. 16th, 1828. Constipation and headache for several days; severe fits of convulsion; insensible in the intervals. Pupils dilated; pulse 80, full and strong; face flushed; os uteri slightly dilated; feeble irregular uterine pains. After venesection and free evacuation of the bowels the fits ceased, and she was delivered the next day, without assistance, of a living child; but it died in 30 hours with convulsions. V.S. \mathfrak{Lxxxv} .; hirudines; head shaved; calomel; enemata. Cured.

CASE IX.—Mrs. W., æt. 33, second pregnancy; ninth month. Oct. 6th, 1828. Had convulsions during her former labour. Headache, giddiness, and drowsiness, during the latter months of pregnancy. Venesection recommended, but not employed. In the first stage of labour, during the night, seve-

ral severe fits at short intervals; muscles of left side most affected; face flushed; pupils dilated; pulse rapid, feeble, irregular; os uteri widely dilated; head pressing through the brim of the pelvis.

7th.—Child born alive this morning without artificial assistance. The fits soon after ceased, and consciousness partially returned. Left side slightly paralysed; pupils dilated.

11th.—No return of fits, and the paralysis is gradually disappearing. From this period she recovered the use of the arm and leg.

On the 4th of January, 1829, she died in a fit of convulsion, with which she was seized soon after taking an emetic, without advice.

Serum was found in the ventricles of the brain. A portion of the upper part of the right hemisphere was in a state of complete ramollissement. Both the cortical and medullary parts of the brain were changed into a thin substance like custard. There were tubercles in the lungs.

V.S. \mathfrak{Lxx} .; cupping, \mathfrak{Lxxij} .; calomel, &c.; head shaved.

CASE X.—Mrs. P., æt. about 25; eighth month. Jan. 27th, 1828. After a violent quarrel with her husband, who came home intoxicated, complained of headache and general indisposition. At 7 A.M. seized with strong convulsions, of which she has had several paroxysms. 11 A.M. insensible; tongue lacerated; a bloody foam issues from the mouth; fits continue, with short intervals, when the muscles are affected with spasm. Pulse slow, full, and strong; os uteri dilated; head of child low in the pelvis. During the continuance of the fits the child was expelled without artificial assistance, at 8 P.M. Afterwards had puerperal mania. V.S. \mathfrak{Lxx} .; V.S. \mathfrak{Lxxvij} . Head shaved; stimulating enema; cupping \mathfrak{Lxxij} .; do. \mathfrak{Lxxij} . Cured.

CASE XI.—Mrs. B., æt. 30; ninth month. April 15th, 1829. Headache, vertigo, great depression of spirits, during the seventh and eighth months of pregnancy. Convulsions: hemiplegia of left side took place seventeen days before labour. Labour natural. Died comatose three days afterwards.

Serum in the ventricles of the brain. A small scrofulous tumor adhering to the basilar artery. A portion of the right anterior lobe of the cerebrum softened, and of a yellow colour.

V.S. $\xi xvj.$; cupping, $\xi xvj.$; do. $\xi xij.$; head shaved; lotions, blisters, cathartics, &c.

CASE XII. —, æt. 30; fourth or fifth pregnancy; ninth month. 1829. Violent convulsions, and insensibility in the intervals, for twenty-four hours, without any sign of labour. After repeated copious venesection, &c., and the fits continuing with undiminished violence, Mr. Stone agreed with me in the propriety of artificial delivery, which I immediately performed by turning the child. Considerable time and force were required to dilate the orifice of the uterus, which grasped the neck of the child so firmly after the body and extremities were delivered, that great force was required to extract the head. The fits ceased as soon as the delivery was completed, and she soon recovered. V.S. from $\xi l.$ to $\xi lx.$; cupping; enemata; calomel; artificial delivery; ice in a bladder to the shaved head.

CASE XIII. —, æt. 20; first pregnancy; eighth month. 1829. Delicate and hysterical; headache and giddiness for several days. From twenty to thirty severe fits of convulsion during fifteen hours; insensible in the intervals; pulse 80; face flushed; bowels costive. Labour came on twenty-four hours after the first attack, and a dead child was soon expelled. No fit after delivery. Consciousness did not return for several days. Uterine and crural phlebitis followed. V.S. $\xi xij.$; V.S. $\xi xx.$; head shaved; ice to the scalp; calomel; enemata. Cured.

CASE XIV. —, middle age; first child; near the full period. March 23d, 1829. Labour commenced four hours before the first fit, which was long and severe. Complained of headache and giddiness for several weeks before. Os uteri fully dilated at 10 P.M.; about the half of the head in the cavity of the pelvis. The pains completely ceased, after the convulsions occurred, till 1 A.M. of the following morning, when they returned, and at 2 o'clock a dead child was expelled.

26th. — Partially conscious; no fits. Attacked on the 27th with uterine inflammation, and died in three days.

Body not allowed to be inspected.

V.S. $\xi xxx.$; leeches, $xij.$; head shaved; lotions, enemata, blisters, &c.

CASE XV. —, a young woman; first pregnancy; ninth month. Sept. 1829. Had frequent and violent fits of convulsion soon after the commencement of labour. Four pints of blood had been drawn from the temporal artery by her medical attendant before I saw her. Os uteri slightly open; no pains. Convulsions continued five hours, when a dead child was expelled. No fit after delivery; but she continued comatose, and died soon after. Copious V.S.; head shaved; enemata; calomel.

CASE XVI. —, æt. 25; first pregnancy; ninth month. April 8th, 1830. Hysteria at the age of 15. At the end of the ninth month frequent fits of convulsion in the course of twelve hours. Consciousness returned after venesection. Severe headache, and occasional spasms of the face and extremities. Labour natural. Uncertain if the child was alive. V.S. $\xi xxx.$; calomel, gr. x.; enemata; cathartics; cold to the shaved head. Cured.

CASE XVII. —, æt. about 20; first pregnancy; ninth month; admitted into the St. James's Infirmary, Jan. 1, 1831. Incoherence, followed by convulsions towards the end of the first stage of a protracted labour. Labour pains strong and regular, and the greater part of the head in the cavity of the pelvis. The fits were relieved after venesection, and she was delivered in a few hours of a dead child, without help. V.S. $\xi xvij.$; V.S. $\xi x.$ Cured.

CASE XVIII. —, æt. 30. May 9th, 1832. Had epilepsy when a child. Labour began at 8 A.M., 7th May. Membranes ruptured in the night; os uteri dilated to the size of a crown on the morning of the 8th. Pains feeble; complained of headache; pulse full and slow. Venesection; enema. Labour continued till the morning of the 9th, when severe convulsion fits supervened. Venesection repeated. Fits and unconsciousness continued for several hours, and the pains went entirely off. The head being still high up in the pelvis, and the os uteri rigid and undilated, craniotomy was performed. No fit after delivery. V.S. $\xi xvj.$; enema; cath.; V.S. $\xi xxxv.$; head shaved; cold lotions; enema; craniotomy. Cured.

CASE XIX. — Mrs. B., æt. 30; first pregnancy; ninth month. Autumn,

1831. Six hours in labour, under the care of Mr. Girdwood, of Paddington. At the end of the first stage of a labour, incoherence, stupor, and several slight fits of convulsion. The symptoms were immediately relieved by venesection, the pains continued, and a living child was soon expelled. V.S. \S xxxvj. Cured.

CASE XX. —, age not ascertained; patient in St. Marylebone Infirmary. December 1831. Had a number of severe fits of convulsion soon after the commencement of labour. No relief was obtained from venesection; and the pains having entirely ceased for many hours, and the head of the child being above the brim of the pelvis, and the os uteri only partially dilated, craniotomy was performed. Only one slight fit occurred after delivery, and consciousness returned gradually. Copious V.S. Cured.

CASE XXI. —, middle age, October 1833, first pregnancy. Had been long in labour, when convulsions came on, without any complaint of headache. A feeble child, born alive. Convulsions ceased immediately after delivery. V.S. \S xxx. Cured.

CASE XXII. —, æt. 20, 30th December; first pregnancy; unmarried. Was called to see a patient, æt. 20, in an adjoining parochial infirmary, who had been attacked with furious fits of convulsion sixteen hours after the commencement of labour. Os uteri fully dilated; head of child jammed in the brim of the pelvis. An ear could not be felt. Fits continued still more frequent and violent after V.S. Pulse rapid and feeble. Labour pains have entirely ceased. Head perforated, and great force required to draw it through the pelvis. No fit after delivery. Sensibility returned the day after. V.S. \S xxx. Craniotomy. Cured.

CASE XXIII. — Kirby, æt. 30, St. Marylebone Infirmary, May 23, 1834. Second child. Pelvis distorted by rickets. Delivered by craniotomy two years before, after a tedious labour. Two strong fits of convulsion took place on the 23d May, when she had been six hours in labour. Fætal head above the brim of the pelvis. Meconium passing. Uterine contractions incessant. Abdomen tense, hard, and painful. Craniotomy. No fits after. V.S. \S xii. Cured.

CASE XXIV. — Mrs. G —, æt. 28, Feb. 25, 1833. First pregnancy, 9th month. After eating roasted pork for dinner and supper, was seized with vomiting, convulsions, and insensibility, at 3 A.M.; after V.S. and an enema the fits became slighter; the pulse extremely rapid and feeble. The fits, however, returned occasionally till 10 A.M., when labour-pains came on. At 1 A.M. a dead child was expelled. Fits and insensibility continued four hours after.

26th. — The fits had ceased and consciousness had returned, though imperfectly. Retention of urine. She died five days after, with symptoms of uterine inflammation. Body not allowed to be opened. V.S. \S xx. head shaved; enmata, &c.

CASE XXV. — A young woman. St. Marylebone Infirmary, July 5, 1833. First pregnancy. Delirium and slight convulsions came on suddenly, after the labour had lasted upwards of 24 hours. Vagina rigid, hot, and tender. Os uteri not fully dilated. V.S. procured no relief. The head being beyond the reach of the forceps, the operation of craniotomy was performed. The fits immediately ceased. Consciousness was not perfectly restored for several days. Copious V.S. Craniotomy. Cured.

CASE XXVI. — A young woman, delivered at 3 A.M., on the 20th May, 1828. Several fits of convulsion soon after, of no great violence.

1 P.M. — Fits have ceased; consciousness partially restored; appears heavy and oppressed, and complains of headache. Pulse 50, full and strong. V.S.

10 P.M. — No return of convulsions. V.S. \S xxv. Calomel, gr. vi. Haust. Sennæ. Cured.

CASE XXVII. — In December 1829, I examined the body of a woman who had died after puerperal convulsions. She was not seen by me during life. Insensibility and convulsions came on during labour, which was protracted. The pulse was stated to have been rapid and feeble. Delivery was completed by craniotomy, and she died comatose three days after. A table-spoonful of serum was found, on inspection after death, at the base of the brain. The pia mater around the tuber annulare vascular. Brain healthy.

CASE XXVIII. — Mrs. M —, æt. 28,

was suddenly attacked with convulsions, eight days after a natural labour. She had ten severe fits in less than two hours. In the intervals she was completely insensible, with stertorous breathing; dilated pupils; the pulse 110, feeble. The fits went off in a few hours, but she remained for several days in a drowsy confused state. The attack followed the use of very indigestible food. Has since been twice confined, and had no convulsions. Cupping 3xii. Calomel; Cathart. enema. Head shaved. Blister. Cured.

CASE XXIX.—Mrs. P——, æt. 26, April 1835. First pregnancy, full period. Returned home after midnight, from a large dinner party, at which she had partaken of a variety of dishes and wines, and had been seated near a large fire. Labour came on at 4 A.M., and soon after she became incoherent, and said she felt her teeth falling out of her head. On attempting to drink some warm tea, she bit a large piece from the edge of the china cup, and crushed it between her teeth. Convulsions of great violence immediately followed. Copious V. S. and an enema gave no relief. In an hour and a half the head of the child was within reach of the forceps, and it was applied, and the child was soon extracted alive. She died at 11 A.M. The perineum was extensively lacerated, from the impossibility of retaining her for an instant in the same position. The child was known to be alive before delivery, from the cord being around the neck and felt pulsating. Body not allowed to be examined. V. S. 3xxx.; V. S. 3xii. Enema. Head shaved. Delivered with the forceps.

CASE XXX. —, æt. 18, unmarried; first pregnancy; end of eighth month. March 3, 1835, St. Marylebone Infirmary, 11 A.M. Has had seven fits of convulsion. Neck and face swollen. Os uteri fully dilated. Face presentation. Pains have nearly ceased. An attempt was made to deliver with the forceps, but it failed, from the impossibility of keeping her steady.

3 P.M.—Fits continuing with undiminished severity, the operation of craniotomy was performed.

4 P.M.—Four fits since delivery, from which she was greatly exhausted. Forty drops of liquor opii sedat. administered, after which the fits became much slighter. The dose was repeated

several times, and the fits gradually went off. V. S. 3xxx.; V. S. 3x. Cured.

CASE XXXI.—A lady, about 26 years of age, who had been in labour with her first child for no long period, was seized with convulsions, for which V. S. was immediately resorted to by her medical attendant. The fits continued with violence till the head was pressing upon the perineum, and it was resolved in consultation to deliver with the forceps. While placing the patient in the proper position for performing the operation, the child was expelled alive by the natural efforts, with the funis round its neck. The fits instantly ceased, but she remained in a state of stupor for ten hours. V. S. 3xxx. Head shaved; enema; cold lotions; cathartics. Cured.

CASE XXXII. — August 1836. A young woman in the St. Marylebone Infirmary had fourteen fits of convulsion in the first stage of labour. It was her first pregnancy. Copious V. S. was employed without effect. I delivered her with the forceps. The child was dead. She had only one slight fit afterwards. Cured.

CASE XXXIII.—Mrs. A——, æt. 25; eighth month; fourth pregnancy. Aug. 17, 1836. Yesterday (the 16th) dined on currie and rice, and ate bacon and eggs at tea.

17th.—Awoke at one o'clock in the morning with violent pain in the back part of the head and sickness, for which she took a strong cathartic. A physician was called to her soon after, and ordered five grains of calomel and an antispasmodic draught, which relieved the symptoms. During the forenoon she remained in a drowsy state without complaining. At mid-day a fit of convulsion occurred. At 3 P.M. another and more violent fit followed. I saw her soon after this. The pulse was extremely rapid and feeble, and it became altogether imperceptible at the wrist on the abstraction of eight ounces of blood from the arm. More blood would not flow from a large orifice in the vein. Orifice of the uterus slightly open; labour pains commencing. Membranes ruptured artificially, and liquor amnii discharged. An hour after, four ounces of blood were removed from the temple by cupping, when the pulse again became imperceptible. At 6 P.M., the os uteri being dilated, and the head in the

pelvis, I delivered with the forceps. The child was dead. The fits continued, and she died at 8 p.m. V. S. 5viii. Cal. gr. x.; Haust. Antip. Cal. gr. xv.; Cupping, 4 ounces. Head shaved. Eucema.

CASE XXXIV. — Mrs. P —, æt. 35, a widow, in the eighth month of her third pregnancy. For fourteen days had influenza and severe headache. At 1 p.m., 8th February, 1837, attacked with convulsions. At 8 p.m. she had had 16 severe fits. V. S. had been employed, and the hair cut off. At 9 p.m., pulse 110, and feeble; hands and feet cold; stertorous breathing. When the fits occurred, the muscles on the right side of the body became first affected. In about a minute the spasms left this side, and the muscles of the opposite side became affected. Pupils dilated. Membranes ruptured. At midnight the fits continued, and the head not being sufficiently advanced for the forceps, she was delivered by craniotomy. Only one slight fit occurred after delivery, and consciousness was restored in the course of the day. V. S. 5xl. Head shaved. Calomel. Encmata. Cured.

THE PURULENT OPHTHALMIA OF INFANTS OF TWO SPECIES.

To the Editor of the Medical Gazette.

SIR,

THE accurate discrimination of species between which there is the greatest resemblance, is one of the achievements of the naturalist which tends most powerfully to promote the advancement of knowledge. Medicine should be considered as a branch of natural history rather than a science; and the distinction would not be without its value, if it led us to imitate the minute and patient observations of botanists in separating allied species, grouping them as new relations are brought to light, and thus step by step advance to general principles; rather than to emulate Newton, and the cultivators of the physical sciences, and mislead ourselves by the hopes of generalizing all our knowledge into one universal fact. Some,

perhaps, may fear that such minute distinctions as the following would tend to overwhelm us with the multitude of species; but the entomologist is not embarrassed by the hundreds of thousands in his department, nor can we help ourselves if nature will not be restricted to our convenience.

In the well-known affection of infants—the purulent ophthalmia—there are reasons which seem to establish the existence of two distinct species, the due discrimination of which has its value:—1. the one depending upon common causes—cold, the presence of some irritating matter insinuated into the eyes during the process of birth, feces, urine, vaginal discharges, &c.; 2. the other arising from the presence of gonorrhœal matter.

The former is of less severity, and most practitioners will agree that it is usually easily and effectually cured by various means. For the most part stimulating collyria of various kinds are used, some preferring one thing, others another. There is no better or more rapidly efficient means, than the old formula of sulphate of copper and bole armeniac, in camphor mixture, termed Bates's lotion.

But not unfrequently a form of the disease is met with of greater intensity, where the matter secreted by the inflamed surface is in immense quantities, the swelling of the lids considerable, and the pain very severe: such cases often resist the above means; and during the attempt to check it, some permanent mischief is done to the eye. There is another serious evil to be apprehended in these cases—the communication of the infection to others of the family, unless obviated by the almost continual removal of the matter, and the very careful separation of other children from the one infected.

When the symptoms of this disease set in with unusual severity, or when our usual means are not speedily answered with success, we may suspect a specific infection; then, and when we know the parents have been infected, more active means must be at once resorted to for its cure. A solution of nitrate of silver, varying in strength from five to ten grains to the ounce of water, according to the severity of the case, will be required. This should be dropped into the eye, and care taken to bring it into contact with the whole sur-

face. It is best to be done by the practitioner himself, or his assistant, twice a day, with strict injunctions to the parents to use very frequent ablutions. If we get the case after it has existed some time, pencil the inner surface of the lids over with the solid caustic, and it will more speedily stop the disease.

This, too, is a known remedy; but I doubt if it be rightly apprehended how generally severe cases are gonorrhoeal, and how much more efficient the nitrate of silver is in these cases than any other remedy. These, however, I think I can confidently affirm, are facts, whatever may be their value. With this impression, the late communications of Dr. Hannay to the *MEDICAL GAZETTE* had a greater interest to me than they would have had if they had stood alone, valuable as they unquestionably are in themselves; and some of your readers may, perchance (when these ideas are suggested), feel the same.—I am sir,

Your obedient servant,

JOHN GARDNER.

49, Great Portland-Street,
Sept. 23, 1837.

EDUCATION OF THE APOTHECARY, IN ANSWER TO DR. KERRISON'S LETTER.

To the Editor of the Medical Gazette.

SIR,

HAVING been for many years a subscriber to your valuable journal, you will, I trust, oblige me by inserting this letter. Dr. Kerrison, in his able letter, has, I fear, not sufficiently considered the degree of attainment necessary in the general practitioner. The Doctor in one part observes, "But it has been doubted whether the routine of study required of candidates for examination has not been too extensive: it might be urged with some plausibility, that the life and health of a poor man are of as much value to his family as those of a rich man, and that, consequently, the qualification of the medical adviser for the poor ought to be as high as that for the rich;" and continues, "the temporal affairs of a man in moderate circumstances may require the judgment of a barrister, yet he must be content to avail himself of the services of a solicitor or attorney, on general occasions, and take the barrister as a referee in cases of importance.

"The spiritual wants of a poor man may require the learning of a bishop, but he must be satisfied with the consolations of religion administered by a curate. The sick poor (not parochial paupers,) and persons in moderate circumstances, may require the judgment of a physician, or skill of an hospital surgeon; but they must be satisfied with the attendance of a gentleman who administers relief in cases of disturbed health and accidental injuries, from which he is called a general practitioner."

Now I consider, Mr. Editor, there cannot be two opinions as to the extent to which the education of the general practitioner ought to be carried: his services are frequently required in cases where the highest skill is necessary, and in which, to delay until a physician or hospital surgeon could be procured, would be highly dangerous to his patient. Any reasonable man who considers this subject, will see directly that it is to the interest of the rich as much as the poor, that the education of the general practitioner should be of the highest stamp, as he is in most cases the first called in, and is expected to be able to treat competently every case.

The Doctor's letter not being intended to provoke controversy, I will here conclude, and have the honour to be, sir,

Your obedient servant,

EDWARD NORTON.

16, Gloucester Place,
Aug. 28, 1837.

DEFENCE OF ANIMAL MAGNETISM.

To the Editor of the Medical Gazette.

SIR,

YOUR journal of the 16th instant, contains an article on Animal Magnetism, in which I am made the object of a personal attack (although my name is suppressed,) and the discovery which I am endeavouring to propagate in this country is represented as a downright imposture. I have been told that, in England, the love of justice is as strong as that of liberty; if this be true, I have every reason to believe that you will not refuse to insert this letter containing my justification.

Accustomed as I am never to flinch

before the opinions of men, but to yield to truth only, the entire press, with its thousand engines of publicity, the whole scientific world, armed with the most plausible and judicious arguments, could never convince me that I am now in error; for, during twenty consecutive years, I myself have witnessed, on more than 6,000 patients, the very facts which are now formally denied.

As my pen alone would be utterly inadequate to the task of defending my name against the powerful attacks of able writers, I shall employ the only means within my reach; I shall exhibit before the multitude the identical facts which are now contested by the learned, and teach every one willing to learn, the right method of obtaining similar results.

I shall prove that the magnetic influence is the more powerful as the individual submitted to its action is less conscious of his being operated upon; and that every human being, when in his natural sleep, is sensible to the magnetic power directed upon him at a distance of several feet.

The opponents of magnetism have found out a word which explains every phenomenon, and consequently saves them the trouble of investigating the subject, *imagination*, a sounding word which only proves the emptiness of their intellect; for, if imagination could heal the sick, it would be their duty to avail themselves of this means. Again, if imagination could produce the extraordinary, not to say wonderful results attributed to magnetism, they should carefully study its powers, since the knowledge of what man is cannot be obtained by any other means.

They shout victory because one magnetizer in a thousand did not succeed in his attempt to prove what he had asserted; but he will be followed by hosts of others who will be more successful, and possess more perfect instruments. They will know better than M. Berna the causes which prevented the success of that gentleman's experiments, and it is those causes which we propose to make known without any reserve.

Science, at the present day, is grown so powerful and omniscient, that no fact can possibly escape her searching scrutiny; but, notwithstanding, we shall claim her aid. We shall proclaim in the face of the world that such

men as Lavoisier, Bailly, Franklin, and a host of scientific men next in merit, unanimously pronounced their verdict against animal magnetism, and yet that species of magnetism does nevertheless exist.

Ye shades of Christopher Columbus, Galileo, Harvey, Jenner!—ye also were condemned; and yet your discoveries still survive, and your names are as imperishable as that of Mesmer is destined to be. What matters it to you if you were misrepresented for a time, when immortality was to be your reward?

The cup of sorrow administered to the man who discovers an important truth, tempers his soul like steel, and only serves to prepare for his brow the crown of immortality.

When men can cope with error and conquer it, humanity has cause to rejoice; but when the learned swerve from the paths of truth, we should not pity, but desecrate them, for the evil they create is beyond all calculation.

As for me, being as fully convinced of the reality of animal magnetism as I am of my own existence, I shall accomplish the task I have undertaken by promulgating the discovery of Mesmer, and spreading the knowledge of its important benefits. I should be wanting in the duty I owe to myself and to truth, should I now neglect answering the virulent attacks which have been levelled at the science I profess, and the public may rest assured that my answer shall suffer no delay. At a future period, which is not very remote, it shall be my turn to attack the adversaries of magnetism, who are well known to me. I shall then expose the secret motives which actuate them; and those enlightened and unprejudiced men who have no private interest in the grand question at issue, shall pronounce their verdict. From this present day, however, I invite all honest and impartial sceptics to come to my residence, and there witness the phenomena produced by me, and watch the progress of the medical treatment already begun on a variety of nervous patients.—I am, sir,

Your obedient servant,

BARON DU POTET DE SUMEROY.

25, Orchard-street,
Portman Square, Sept. 21, 1837.

[We have thus inserted the letter of

M. du Potet; and in answer to his remarks, have only to refer him back to our article which called them forth, and which he has left wholly untouched.

We perceive that a verbatim copy of the letter was also sent to the *Globe* newspaper, the Editor of which states that he gave it insertion for "*amusement.*" We trust the worthy Baron duly appreciates the compliment. — *Ed. Gaz.*]

MEDICAL GAZETTE.

Saturday, Sept. 30, 1837.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

A PROSPECT AND A RETROSPECT.

WHEN we published the last number we had completed our tenth year, and the twentieth volume of this journal. Our readers will, we hope, bear with us while, before entering upon another period, we cast a rapid glance back on our past course, and some of the events that have occurred in its progress.

When the publication of this journal was commenced, it seemed to many impossible that a weekly journal, conducted on other principles than those involving the destruction of existing institutions, and without personal rancour, could exist for a single year. Although we thought otherwise, we were still not so confident in our opinion, but that, in our original address, when speaking of some seemingly popular practices which we expressed our determination not to imitate, we said — "Whether our experiment will succeed, time only can tell."

Time has told what we can now with the greatest satisfaction repeat to our readers—that the *experiment* has succeeded completely. Without one check,

without the slightest vacillation, the circulation of the *MEDICAL GAZETTE* has regularly and steadily increased, from the first year of its publication; and this, be it remembered, while in the most unwearied manner we have adhered to the principles and plans with which we commenced our career; not wantonly attacking any, yet never withholding the honest expression of our opinions on public men and measures, when they appeared to us to require it; nor ever relaxing in our efforts to be really useful to our profession at large.

Our prosperity is a strong presumptive proof in favour of the means we have employed to obtain it; and such a result will always, we believe, attend such means. Others may thrive by following a very different course. But at this who will complain? Not we. With gratitude for our past prosperity, we shall *repeat the experiment*, on the same plan, and with similar materials. We have now the useful experience of ten years to guide us; the surrounding atmosphere, too, is far more favourable than when we commenced our task: the storms which we had then to encounter have lulled into what might seem by comparison a perfect calm; the scorching and rancorous heat has given way to a more mild and equable temperature. *Deo volente*, we hold it certain that the success of our second decennial period will even surpass that of the first.

In proof that we had striven to deserve success, we may briefly enumerate some of the most important matters which we have published, as contributions to the stores of medical science.

Of systematic courses of lectures, we have given those on Surgery, by Mr. Lawrence—on Medicine, by Dr. Elliotson—on Midwifery, by Dr. Ramsbotham—on *Materia Medica*, by Mr. Pereira—on Forensic Medicine, by Pro-

fessor Amos and Dr. Cummin—the latter alone remaining as yet incomplete.

Of Clinical Lectures, we have published several series by Sir Charles Bell and Sir B. Brodie, and numerous others by Mr. Arnott, Mr. B. Cooper, M. Dupuytren, Mr. Earle, Dr. Graves, Mr. Guthrie, Mr. C. Hawkins, Mr. Key, Dr. Latham, Dr. Mackenzie, Dr. Seymour, Mr. Travers, and Dr. Watson.

Among the shorter courses of Lectures, or Essays, will be found those of M. Andral on the Brain, Mr. Bacoet on Syphilis, Baron Heurteloup on Lithotriety, Dr. Birkbeck on Mechanics, Messrs. Brett and Bird on Urinary Concretions, &c., Dr. Bright on Abdominal Diseases, Dr. Buchanan on the Animal Fluids, Dr. G. Burrows on the Pathology of the Blood, &c., Dr. Chambers on Fever, Dr. Davies on Diseases of the Chest, Mr. J. W. Earle on Inflammation, Sir H. Hallford's College Orations, Dr. Bisset Hawkins on Medical Statistics, Dr. F. Hawkins on the Brain, Dr. Hope on Diseases of the Thoracic Viscera, Dr. Hugh Ley on the Pathology of the Nerves, M. Magendie on Physiology, Mr. Middlemore on Diseases of the Eye, Mr. Mayo on Morbid Anatomy, Dr. Wilson Philip on Digestion, on the Use of Mercury, and various other subjects, Dr. Prout on the Medical Applications of Chemistry, Dr. Rigby's Obstetrical Reports, Dr. Roget on Sensation and Perception, Dr. Roupell on General Pathology, Dr. Seymour on the Ovaria, Mr. Stanley on Diseases of Bone, Dr. Williams on Animal Heat.

These gentlemen have all, too, been contributors to our pages on various subjects not connected with their lectures; and among a crowd of more or less frequent correspondents, it may be sufficient, as a sample taken from memory, to mention Dr. R. Lee, Mr. Swan,

Dr. Gregory, Mr. Copland Hutchison, Mr. Owen, Mr. Shaw, Dr. Clendinning, Dr. Marshall Hall, Dr. Baron, Mr. Robertson, Dr. Hamilton. In short, it would scarcely be easy to find a name of repute, either in the metropolis or provincial towns, that might not be placed in one of these lists.

Surely it will be granted, then, that we have fulfilled the promises that have at various times been made in regard to this portion of our plan, and have at the same time afforded some important assistance to medical science. For it will be observed that many (of the lectures for example), which are mentioned above, have been, as it were, snatched from most unmerited oblivion; because, in some instances, they are the works of those who have never published at all in any other form. Many others, it will be seen, are the first fruits of the labours upon which have since been formed some of the most esteemed and standard works in modern medical literature.

One other remark we may make here. On looking over the list of names given above, it is impossible not to be struck with the fact that there is scarcely one among them whose possessor has not increased in reputation since the appearance of his works in our pages. We see the names of many there, who, when they were first contributors to our journal, were scarcely known; some who were only "rising men," are now placed at the very highest elevation in their profession, and most of the others are rapidly following them in their successful careers. We are not so absurd as to claim to ourselves the merit which belongs to them; but the more rapid progress of some has so immediately followed the publication of their early works here, as at least to show that the seed had not fallen on an unpropitious soil.

Among the subjects more immediately belonging to our own department, and which have been handled during the last year, we flatter ourselves that the exposure we made of the filthy puerilities and incalculable absurdities of homeopathy, had considerable effect in extinguishing that folly in this country; and we have recently put a spoke in the wheel of those who would roll themselves into notoriety by means of animal magnetism. To quackery in every shape, it must be acknowledged even by those who differ from us in politics, that we have ever been determined and active opponents; while we have exerted ourselves, and we trust not unsuccessfully, to support the welfare of the profession at large. We may on this point more particularly instance our exertions in connexion with the Poor Laws, which so severely affect the interests of the general practitioner. A very large number of our articles on these and other subjects have been deemed of sufficient interest and importance to be copied into the public papers.

The limits of the present article would be insufficient to give even a sketch of the progress which medical science has made in the last ten years; but on looking through our pages, we are forcibly struck with the idea that, in no period of the history of scientific medicine, could any equal length of time be found during which so many and so valuable individual facts were collected and recorded, and yet so few great discoveries or generalizations achieved. And it must be allowed, that in the present condition of medicine, this is by far the most satisfactory state. Till lately, the department of medical literature rendered most conspicuous by the talent and reputation of its authors, consisted of systems almost as theoretical as they professed to be complete; and the facts which they contained, collected solely with reference to one or

other of the theories, were what Cullen called all but those that served his own—"false facts." Hence the majority of the great discoveries in medicine were accidental, and, with but few honourable exceptions, the records of facts could not safely be made use of for the establishment of sound generalization. The history of medicine only agrees with that of other sciences in showing a deficiency of positive evidence to be an abundant source of theories. It is remarkable that the error of the system was not earlier discovered, and that the last ten years should have been the first to witness the prevalent existence of a spirit tending to correct it.

The prominent character of the medical records of this period has been the complete detail of facts which they afford. Physiologists have attended comparatively little to life, to vital principles, to nervous influences, and other such subjects, which not long since occupied unprofitably their chief attention; and proximate causes, nosologies, and *modus operandi*, are comparatively obsolete terms: all are now engaged in collecting actual and indisputable facts. Already a vast body of evidence in all branches of medicine is accumulated, and though the labour may be less agreeable than the more exciting and self-complacent occupation of former days, the workmen are already receiving their reward in the establishment of important and well-determined results: if persevered in steadily for but a few years more, it cannot be doubted but that medicine will by this plan be placed among the more certain sciences, and that on the best foundation of inductive reasoning, a number of general principles of the highest importance in their application to practice will be attained. Every student may be happy that he has fallen on what will in future ages be called the spring-time of the philosophy of medicine; and in re-

turn for the benefits which he derives from the improved system of its study, let him contribute in the same spirit his share of the evidence which alone is now necessary to secure the advance of the science.

Passing from medical science to another subject which has occupied the remainder of our pages—medical politics and medical institutions—we have no less cause for satisfaction. It was predicted that if we did not fall by our own weakness, we should soon be buried under the ruins of the institutions which we supported, and with which some of our principal contributors were connected: but this has been as false a prophecy as the rest. The great and only important innovation is the establishment of a New University, which it has occasionally been imagined might exercise an injurious influence on the older institutions. This, however, is now no longer probable, and we shall only further remark, that while we, in common with many others, strongly advocated the expediency of a University in London, yet, so far does the present one differ in almost every feature from that which the original advocates of the change had proposed, that like us they have silently, but almost entirely, withdrawn their support. We still, however, live in hopes of seeing what appear to us to be its blemishes removed, as we do to certain vices in the older establishments being thoroughly reformed. It would be the height of injustice, however, not to admit that the College of Surgeons has made great and rapid strides in the course of utility and improvement.

In medical education, the only important alteration has been the increased amount of study demanded by the Apothecaries' Company—a change of very doubtful utility; but on this point we expressed our opinions in a very recent number.

Amid this gratifying retrospect, one thought alone occurs to mar our satisfaction: how many has this same period removed from their scene of usefulness! Abernethy, Lynn, Babington, Blizard, Maton, Warren, Tuthill, Pearson, Gooch, Ley, Darwall, from our brethren and familiar friends; and then again, Wollaston, Davy, Young, Turner; and abroad, Scarpa, Dupuytren, Boyer, Hufeland, Rudolphi, Portal, Gall, Spurzheim, and Lobstein. When we look back on the past, which from the other points of view seems lengthened by the number of events which are crowded in it, it seems in this aspect but as a day; all these seemed to have "gone in a moment,"—and they are but a few, and only such as were known and esteemed by the world; but how many thousands more have passed from the stage on which, though it were smaller, they shone with equal lustre, and where they have left not less endearing memorials.

But in the household of science it is the children alone that are mortal. Increasing age sees the mother only more prolific, and the offspring of each succeeding year more vigorous and worthy of their parent. Journalists, her and their servants, so long as they are faithful to their duty and to science, share the perpetuity of the mother; and though with her they may lament the loss of each of her departed sons, it becomes them to be no less anxious for the welfare of the present than of the past. For ourselves, as we have done in times gone by, so shall we continue to do in those which are to come—still holding to our old motto—"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

MR. PEREIRA'S LECTURES.

THIS very valuable course of lectures on *Materia Medica* and *Therapeutics*, was concluded in our last number. Although they have been contained in seventy-four numbers of the *GAZETTE*, yet as in many instances two or more lectures were given, extending through ten or twelve pages, the actual amount of the course exceeds 100 lectures, each occupying between six and seven pages of the *GAZETTE*, and illustrated by above two hundred woodcuts. They thus form by far the most complete system of *Materia Medica* ever published in this country.

BRITISH ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE*.

WE gave a short account last week of the papers connected with medical science, read at the late meeting at Liverpool. Elaborate reports of all the proceedings have been published in several papers, and we shall therefore content ourselves with giving a sort of catalogue *raisonné* of the chief contributions connected with medicine.

Tuesday, September 12th,

Dr. BLACK read an essay on the *Epidemic Influenza*, as it occurred in January, February, and March, 1837. This paper chiefly referred to the rate of mortality, and the meteorological condition of the atmosphere, for which purposes several elaborate tables were exhibited. It appeared, in comparing the mortality of the period above mentioned, with the corresponding months of previous years, that the increase amounted to 45 per cent., and taking the month of February alone, to the prodigious extent of 160 per cent. Dr. Black's observations fully confirm those previously made, of the very heavy manner in which the epidemic bore upon those advanced in life: and he referred particularly to the reports published in this journal, by Drs. Clendinning, Heberden, and Graves.

* By rather a ridiculous oversight, the account of the meeting of this institution in our last number, was headed "British Medical Association," whereas the club, which rejoices in this name, is one of a totally different nature, and having totally different objects.

Wednesday, September 13th.

Sir JAMES MURRAY. — A paper, the object of which was to prove that various diseases of the nervous system arose from the presence of certain salts in the blood giving rise to crystalline deposits, such salts being those which are usually voided in the urine. Such depositions he has found on the nerves in *tie-douloureux*, and has also detected uric acid in the discharge from ulcers in *tinea capitis*, and some other cutaneous affections. Our readers will remember that M. Gluge has recently described microscopic crystals in the evacuations of persons labouring under fever (see last volume, p. 246.)

Dr. MACINTOSH made some observations on *Dysmenorrhœa*, which he endeavoured to shew originated in a peculiar condition of the os uteri—viz. some degree of stricture, with thickening and the deposition of false membrane, and accumulation of mucous discharge in the uterus itself. He stated that he had frequently seen great benefit result from the application of leeches to the os uteri.

Dr. MADDEN — Experiments on the *Connexion between Nerves and Muscles*, the result of which he regards as shewing that narcotics do not always produce any obvious effect upon contractile tissues; that sedatives, when applied to nerves, are absolutely inert, if such application be rigidly confined to the nerve; and that muscles retain their irritability long after the nerves have lost their power of exciting them.

Dr. BELLINGHAM on the *Motions of the Heart*, with especial reference to the order of their succession, which he holds to be as follows:—1st, the systole of the auricles; 2d, diastole of the ventricles, and the simultaneous impulse; 3d, the systole of the ventricles; 4th, an interval of repose, followed by the systole of the auricles. This order is different from that given by Dr. Hope.

Sept. 14, 1837.

A report was read by Dr. CARSON, on the *Composition of the Animal Secretions*, giving the results obtained by a provisional Committee appointed to examine the subject.

Mr. HARE read a paper on *Curvature of the Spine*, particularly the lateral, which he attributes to the present mode of dress—in a word, to tight stays. The means proposed by Mr. Hare consist of

an inclined plane, with weights and pulleys, similar to those which have been so much used during the last ten or twelve years.

Dr. HOLLAND, of Sheffield*, communicated the result of some investigations regarding the *Influence of the Mind on the Heart*. This paper chiefly had in view the influence of respiration on the circulation, the former of which he stated to be greatly under the control of emotions which secondarily affected the circulation. The positions were illustrated by various arguments.

Dr. MACINTOSH communicated some observations (which were understood to be from the pen of a medical student), on the *Diseases of Stonecutters* about Edinburgh. In one case, which was particularly detailed, the patient having died after cough and other pectoral symptoms, of two years' duration, hard black tubercles were found in both lungs; the bronchial glands enlarged and indurated, grating under the knife, and containing portions of substance like bone, which, being analysed, yielded carbonate of lime, silica, and albumen. The stone of the quarry where he had chiefly worked was also examined, and found to consist of carbonate of lime, silica, and alumina; from which it is inferred by the author that the deposition in the lungs was derived from the stone, and imbibed during inspiration.

Sir JAMES MURRAY made a demonstration of a machine for forming a kind of *Bath in Vacuo*, by which means the surface of the body, even when cold and collapsed, soon became warm and turgid. It admitted of being used locally, as to a paralysed arm, &c.

Two cases of *Malformation of the Brain* were communicated by Dr. CARLISLE, and some remarks on the crania of a tribe of Indians in North America, by Dr. WARREN, of the United States.

Dr. MACINTOSH on the *Morbid Anatomy of Cholera*.—He observed, that he had made 300 dissections of patients who had died of this disease. He found the capillary system generally distended with blood—the brain loaded—the bones themselves vascular; the ganglia healthy, but vascular; the heart and its vessels turgid; false membranes lining the arteries, the

finer the nearer the heart; an appearance which he regarded as somehow connected with an effort on the part of nature to restore the deficient serum.

In the department of Zoology, Dr. RICHARDSON communicated a paper from Dr. BELLINGHAM, on the frequency of the occurrence of the *Tricocephalus dispar* in the alimentary canal. He regarded it as premature to attempt the decision of whether this parasitic animal was or was not formed in the intestines.

Mr. JENYNS communicated a paper from Dr. WILLIAMS, on a species of *Linax* found in the human intestines.

The meeting seems altogether to have been a very good one. Next season the Association is to assemble in August, at Newcastle-upon-Tyne; on which occasion the Duke of NORTHUMBERLAND has consented to act as President, and the Bishop of DURHAM as Vice-President.

ST. BARTHOLOMEW'S HOSPITAL.

Rupture of a Muscle.

SEPTEMBER 13th.—A butcher came to the hospital, carrying in the palm of his hand about half the tendon, and a portion of the muscular tissue of his flexor longus pollicis. He said, that jumping down from a raised board he had caught himself on one of his meat hooks by the palmar or surface of his wrist; it had hooked under the tendon of the flexor longus pollicis, and had passed, tearing its way along the ball of the thumb; and the tendon not breaking through with his weight, suspended from it, its flattened expansion had been pulled completely out from the middle of the muscle attached to it. There was no wound of the fore arm visible externally, and the distal end of the tendon still remained attached to the last phalanx of the thumb, close to which it was cut off, and the wound of the palm dressed. Some few short portions of muscular fibre were still attached to the tendon, and life was not yet, after several minutes had elapsed, extinct in them; for when he first arrived they were lying soft and flaccid on the tendon; but when thrown into cold water they crimped up, and still, after five days, remained at right angles to the surface of the tendon, and firmly contracted.

Corpus Luteum six months after delivery.

September 11th.—On examining the body of a young woman, 22 years of age,

* It was *this* Dr. Holland's paper of which we gave a short notice last week.

who had died of dropsy, with disease of the kidneys, supervening on scarlatina, an elevation being observed on the surface of the left ovary it was cut open, and found to present the cicatrix of a corpus luteum, though it was now six months since she was delivered of the child which she was suckling, till within a short time of her death.

The elevation visible externally was raised about a line and a half from the surface, and formed part of a rounded body, between three and four lines in diameter, of a firm and dense structure, presenting, in its centre, a white radiated cicatrix, surrounded with a dark-greyish substance passing between and marking the outline of the rays of white. In the centre of the cicatrix there was an indistinct grey small spot. On the surface of the elevation a small piece of tissue, like a membranous adhesion, hung loosely, and in the same ovary there was a cyst filled with a grumous yellow matter.

The appearance of the cicatrix was almost precisely that described and figured by Dr. Montgomery, in his work on the "Signs of Pregnancy and Delivery," as found in the body of a female who had died five months after delivery. The minute yellow spot, however, was not visible here, and the outline of the radiated cicatrix was better marked.

The kidneys were the only organs found diseased; they were of very large size, presented the morbid yellowish deposit described by Dr. Bright, in an advanced degree, and on injection were found far less vascular than usual.

Irreducible Dislocation of the Hip.

August.—A fine young man, of 33, was brought up from the country with a dislocation of the hip of six weeks' standing. The surgeon who had first seen it had not been able to detect any such injury. The day before his admission an attempt at reduction was made, without success. Two days after, a second was made by Mr. Stanley, with every possible care; he was bled to fifty ounces from the two arms; and had, while extension was being made, four grains of tartar emetic given him, which together reduced his muscular strength to such a degree, that the pressure of his robust hand could scarcely be felt. Constant and steady extension by the pulleys was maintained for an hour and ten minutes, and the head of the bone was drawn from the dorsum of the ilium completely to the level of the acetabulum; but no effort could force it into that cavity; and on suddenly cutting the pulley-ropes, and simultaneously abducting the thigh, it passed back to its previous situation.

Notwithstanding that in this attempt every favourable circumstance seemed to have been present: the man expressed so strong an anxiety that further efforts should be made, that in the next week a third endeavour was made, but with as little success; a fourth was added a few days after, but it only tended to confirm the probability, that some mechanical obstacle (perhaps a portion of the torn capsular ligament) is lying over and closing the acetabulum.

He has, therefore, left the hospital unrelieved, though the head of the femur seems to have formed a new articulating surface; and there is tolerably extensive motion of the limb; but shortened as it is nearly two inches, he is of course deplorably crippled.

Strangulated Hernia.

September 11.—Mr. Lawrence operated on an old woman, for a small femoral hernia in the left side, which she said had been down only two days.

It had been intended to attempt a reduction of it without opening the sac, but this was found not possible, and there was some difficulty in determining when the sac was opened, for on exposing what seemed to be intestine, its surface was found rough and filamentous. This was discovered to be a firm but thin layer of organized lymph, closely adherent to the peritoneal surface of the intestine, and uniting it tightly to the walls of the sac. A portion of coagulated blood effused into it, had at first had the appearance of a gangrenous spot on the gut. The adventitious membrane being dissected off, and removed from its connexions to the two serous surfaces, the exceedingly light structure formed by the anterior edge of the superior process of the fascia lata was divided, and the intestine now easily returned. A considerable quantity of serous fluid flowed out of the abdomen by the wound.

The case was remarkably one of those in which it would have been impossible to return the intestine except with great violence and harm, without opening the sac.

Rather severe peritonitis coming on at night, six dozen-leeches were applied at different times, and the patient has since gone on well.

LONDON HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

You did me the favour some time since to publish a monthly report of the frac-

tures admitted into the London Hospital: and as I understand the subject has interested some persons, I have endeavoured, as well as I could, to arrange at one glance the whole of the cases admitted during six months entire. I admit freely that it is still very imperfect; but I have ascer-

tained as accurately as I could, the ages of the respective patients. But as I, in many instances, could not arrive at this point, I have drawn the conclusions from those whose ages are authenticated. If you deem it of sufficient interest, you will oblige me by its insertion.

Case.	No.	Comparative Ages.
Cranium	12	Varying from 9 years to 48. From 28 years to 52. From 17 years to 71. { From 19 years to 74: of these, four-fifths were above 40, at which period the elasticity of bone may be considered as much decreased*. Adults.
Upper jaw	3	
Lower jaw	3	
Spine	5	
Pelvis	4	
Ribs	50	{ From 9 months to 60 years of age; half of which are under 12 years, and the bulk of the remainder from 20 to 30. From 4 years to 50, of which one-third are under 12: of the remainder, the greater number range from 18 to 40. { From 4 months to 70 years; nearly one-third under 12. From 19 months to 79 years. One-sixth occur under 12, and a very large proportion above the age of 50; many of these cases being fractures of the cervix. { From one year and a half to 72; one-ninth occur under 12; one-fourth above 50.
Sternum	2	
Scapula	7	
Clavicle	50	
Humerus	34	
Fore-arm, one or both } bones	43	{ From 19 months to 79 years. One-sixth occur under 12, and a very large proportion above the age of 50; many of these cases being fractures of the cervix. { From one year and a half to 72; one-ninth occur under 12; one-fourth above 50.
Hand, metacarpus, &c. ..	17	
Femur	27	
Leg	66	
Patella	4	
Foot, &c.	6	
Total	333	

In attempting to form a comparison as to the side of the body more liable to particular fractures, it appears that, taking a general view of the whole, the left side seems most obnoxious to fracture; and this is more especially observable in the fractures of the ribs; whilst nearly an equal preponderance in favour of the right side exists in reference to the leg and forearm.—I am, sir,

Your obedient servant,
JOHN ADAMS.

31, New Broad-street,
Sept. 21, 1837.

* Half are above 50 years of age.

WESTMINSTER HOSPITAL.

Purpura Hemorrhagica—Fatal.

WILLIAM HUNT, æt. 45, admitted January 13th, under Dr. Bright. On the elbows, down the course of the spine, inside of the thighs, and generally over the legs, the purple *maculæ* are dispersed: in some places the patches are so large as to seem like the result of bruises. The colour is most decided in the centre of each spot, and gradually fades towards the margin. The pulse is 84, feeble; tongue clean; bowels torpid, motions clay coloured; urine scanty and high coloured, depositing a sediment like carmine. The man has a sallow complexion; the white of the

eye is tinted gamboge. There is no tenderness in the hypochondrium. The abdomen is tense over fluid. The legs are œdematous.

Hunt is an old soldier; he served in Spain and at Walcheren. At this last place he had the well-known epidemic. Being an habitual drunkard, he was exposed, about six weeks before admission into this hospital, to cold, whilst in a state of inebriation. When he came to himself, he had pain in the right hypochondrium and throughout the muscles of the body; these symptoms gradually evanished, and were succeeded by dropsy of the belly and legs. Contemporaneously an attack of hæmoptysis occurred. About a week before he showed himself at the hospital, the petechiæ just described made their appearance. Ordered the following medicines:—

R Ext. Coloc. Comp. gr. x. hæc nocte et pro re nata sumend.

R Pulv. Rhæi, gr. iij.; Pulv. Cinchonæ, ʒj. M. fiat pulv. ter die sumendus.

Decoct. Cinchonæ et Acid. Nitric. 6tis horis.

January 14th.—The abdomen is still tense; water not increased; bowels confined.

Rep. Pulv.

15th.—The petechiæ unaltered; copious rosaceous deposit falls from the urine; anasarca swelling of the legs diminished.

16th.—Fresh petechiæ have appeared on the calves of the legs. The older petechiæ are of a paler colour; the œdema has diminished; abdomen still tense; urine of a dark madder colour, depositing the purpura of ammonia. During the day considerable hæmorrhage took place from the lungs. *Calomel and squill pills* to be taken daily, and cream of tartar solution to be drunk *ad libitum*.

17th.—The purple spots have diminished as regards intensity of colour. Epistaxis took place to some extent this morning. The bowels torpid. To take a dose of spirit of turpentine, qualified with oil of peppermint.

18th.—Complains of some pain in the left side, increased on coughing. The purpura has appeared in some fresh places. The bowels are freely open.

20th.—Bowels again torpid, the maculæ spreading generally over the back. Urine increased in quantity, but of the same madder-like colour, and still depositing the purpura.

23d.—The patient much harassed by cough. The sputa consist of mucus, floating in a greenish fluid. The yellowness of the eye has remained undiminished. The urine has increased to three

pints daily. To be purged with jalap and calomel.

24th.—Abdomen less tense. The maculation diminishing in colour and extent; urine clearer, and more lightly coloured.

25th.—This morning about nine o'clock sudden hæmorrhage from the mouth occurred. It proceeded apparently both from stomach and lungs. The blood was of a bright vermilion hue, and streaked with dark lines. The face of the patient is contracted. Pulse very weak. Laudanum and dilute mineral acid is administered in proper doses.

10 A.M.—The hæmorrhage returned in ten minutes after the exhibition of the draught, to the extent of nearly a quart. No pulse was perceptible at the wrist. A glass of wine given. The hæmorrhage remained uncontrolled, and the patient died at half-past ten o'clock.

Sectio cadaveris, thirty six hours after death.—The entire body was dotted with petechiæ, and all the surface was of a yellowish tint; the lungs were slightly œdematous, but in other respects healthy. The mucous surface of the stomach, and small intestines throughout, covered with blood: this membrane, when sponged, was of a red colour, and infiltrated with blood. The liver was granular, and adherent by membranous bands to the adjacent viscera. The gall bladder distended with bile; the cystic duct thickened, and almost imperious. The contents of the gall bladder consisted apparently of blood mixed with cystic bile of a sweet mawkish taste; staining red rather than yellow. The surface of the gall bladder was ecchymosed; all the other viscera were sound, except the muscoli recti abdominis, which were completely infiltrated with blood.

Gangræna Pulmonum.

Francis Wright, admitted 22d January. This man, 58 years old, complained, when admitted, of great debility and unceasing nausea, bringing on frequent vomiting. He had pain in the epigastrium, and occasional expectoration of blood; the sputa had an offensive smell, and the patient had a troublesome cough; there was no appetite, and no food but milk was taken; pulse 90, and jirking; the countenance was natural, not indicative of suffering.

About a week previously, whilst walking in the street, he was suddenly seized with sickness. This feeling was almost immediately succeeded by a sense of suffocation, and a hæmorrhage from the mouth of bright arterial blood. For two months previous to this event he had felt a constant and dull pain under the sternum; this was much increased on motion, but it almost

entirely ceased on lying down. He could recline on either side.

The breath of the patient has an offensive fœtor. The sputa consist of little, rounded, blackish grey masses, occasionally tinged with blood. Percussion elicits sounds clearer than natural over the superior part of the *right* lung; over other parts of the thoracic hemisphere the resonance is good. Cavernous respiration is evident in the apex of the lung. In the subclavicular and mammary regions of the same side, the vesicular murmur is indistinct. In the lower portion of the lung this sound is perfect.

The sounds brought out by percussion on the *left* side are quite normal. The respiratory murmur is of a *purile* character. Bronchophony is evident in the apex of the lung.

21th.—The odour of the patient's breath is so great, that the ward is offensive to the other patients. The bowels have been opened with castor oil. He is ordered infusion of roses and muriatic acid, and a blister is applied to the sternum. The chloride of lime in solution is placed under the bed. Strong beef-tea is to be allowed twice a day.

27th.—The patient's breath is not so fœtid as before; the cough and expectoration unchanged; the pulse 50, and feeble; the bowels are open. He states that he feels better. The auscultative symptoms are unaltered.

Milk diet, and the following medicine:

R Sol. Chlor. Sodæ, ℥ss.; Aquæ Distillatæ, ℥viiss. M. sumatur ℥j. 4tis horis

29th.—He cannot take the chloruret mixture because it nauseates him. He is to recur to the acid mixture. The breath is as offensive as ever. Bowels regular; tongue moist and clean; pulse small and feeble; expectoration viscid, purulent, and of a dark blown colour. The dull sub-sternal pain has increased.

31st.—Great thirst is now added to the other symptoms. He is nauseated by the offensiveness of his own expectoration.

Feb. 4th.—The patient complains of great prostration. Diarrhœa has supervened on the already described symptoms. The stools are fluid and graveolent; the pulse 90, weak.

6th.—Very weak; he is rapidly emaciating. He is ordered to have quinine and rose infusion.

9th.—The debility is getting hourly more obvious. The fœtor of the expectoration produces such continual nausea that he cannot take any nourishment; the breath is most repulsive. The respiration is short and hurried; 40 per minute. The

tongue clean, red, and moist; pulse 110, very small.

6 P.M.—The patient cannot articulate two words; he is rapidly sinking.

10th.—He died this morning.

Autopsy, 24 hours after death.—The patient's body is a good deal emaciated. On opening the thorax the appearance of the lungs, *in situ naturali*, was not unhealthy. These viscera did not collapse, and their superficies presented their usual bluish mottled appearance. Bands of recent lymph connected the inferior lobes to the diaphragm; patches of lymph were also deposited on the middle lobe of the right side. The *left* lung was not adherent to the costal pleura. On the *right* side the apex of the lung was attached by old inseparable adhesions; and the attempt to break through them opened a cavity in the substance of the lung, near the apex, about the size of a *tea cup*. This contained a dark green viscid fluid, in which were pieces of sphacelated lung as large as hazel nuts, some detached, and some adherent to the flimsy remains of the bronchial ramifications. The fœtor was scarcely tolerable. A smaller cavity of the like kind, and having similar contents, was found at the inferior margin of the middle lobe. A few miliary tubercles were dispersed through this lobe. The apex of the left lung contained also a few tubercular deposits, and there were generally traces of the grey hepatization.

The liver was enlarged and granulated. No other pathological phenomenon worthy of notice existed in any part of the body.

NEW TEST OF THE PRESENCE OF MORPHIA.

M. LAFARGUE has presented, during the last month, papers to the French Institute, to show that an invariable and very delicate test of the presence of morphia in fluids, is to be found in inoculation. He has tried infusions of several of the species of poppy which contain that principle, and of their congeners which do not; and he finds invariably that a small quantity introduced under the skin, as in vaccination, is followed by the development of a papula of determinate character.

SWEATING OF BLOOD FROM THE FEET IN TERTIAN FEVER.

DR. KAMINSKY has communicated a very curious case of this affection.

The father of a girl in the country, who was suffering from tertian fever, was alarmed, not only at the fever, but parti-

cularly at a transudation of blood from the feet from one day to another. On an accurate inquiry, it appeared that the girl, who, from description, had been of a strong and plethoric habit of body, had never menstruated. The blood flowed in considerable quantity on the days of the fever, with the accession of the hot stage, from both feet, from openings caused as if by leech bites, and again ceased gradually after the paroxysm was past. By an appropriate treatment, particularly by the employment of quina, which this physician gave in combination with carbonate of magnesia, carbonic acid, and rhubarb, the fever soon disappeared, and along with it the bleeding at the feet. After pediluvia had been employed for some time, menstruation appeared.—*Provincial Returns of Health of the Royal College of Medicine, Pomerania*; and *Dublin Journal*.

NEW GENUS OF NEMATOIDEA.

On examining the stomach of a fine young tiger belonging to the Zoological Gardens, Regent's Park, which died some time ago, two worms were found in it, one of which forms the type of a new genus of *Nematoidea*. Some of the worms measured nearly an inch in length, and a line in thickness; others being more minute. Only a pair of the larger were found, the smaller species existed in countless numbers; they were found in tumors. The mouth of these creatures is surrounded by a tumid circular lip, armed with six or seven circular rows of well-developed spinous processes of a complex structure. The oral orifice itself presents the form of a vertical elliptical fissure, bounded on each side by a jaw-like membranous fold or process, the anterior margin of which is produced in the form of three straight horny points directed upwards, which can be protruded beyond the circular lip by compressing the smooth spineless skin beyond the latter, and the elasticity of the structure causes them to be again retracted on remitting the pressure. The surface of the body appears to the naked eye to be minutely striated transversely; it is variegated by the white genital and amber-coloured digestive tubes appearing through the transparent integument. When examined by a lens of half-inch focus, the anterior two-thirds of the body are seen to be covered with circular series of minute reflected spines, which, viewed with a still higher power, present three distinct points, one large one in the middle, and two small lateral ones.—*Morning paper*.

SIGNS OF DEATH.

M. DONNE has pointed out, as the only certain mode of ascertaining that death has taken place, a short time after the event, the examination of the blood globules. In these, he says, putrefactive changes take place long before any alteration can be discovered in the tissues. He intends soon to present to the Institute a full detail of all the changes to which they are subject, and their distinctions from those occurring during life.

NEW MEDICAL WORKS.

The Surgical Works of John Hunter, with Notes by J. F. Palmer. 3 vols. 8vo. with Plates, 2l. 12s. 6d.

The Nature and Treatment of Diseases of the Ear. By Dr. W. Kramer. Second Edition of the Author's Treatise on Chronic Deafness, much improved and enlarged. Translated from the German, with the latest improvements of the Author, since the last German edition, by J. R. Bennett, M.D. &c. 8vo. 10s. 6d.

A Treatise on Operative Surgery, by W. B. Cocks. Illustrated by 12 plates, representing 64 Surgical Operations, &c. 8vo. 11s.

The Chemical Decompositions of the London Pharmacopœia. By J. Steggall, M.D. 12mo. 3s.

Celsi di Medicina opera elente et enarrata J. Steggall, M.D. 12mo. 7s.

Medico-legal Treatise on Homicide by External Violence, with an Account of the Circumstances which modify the Medico-legal Characters of Injuries, and Exculpatory Phases. By Alexander Watson, Esq.

The Philosophy of the Eye. By John Walker.

Mr. Grainger on the Structure and Functions of the Spinal Cord. 8vo. 7s.

The Philosophy of Health. By Southwood Smith, M.D. Vol. 2, 12mo. 7s.

Encyklopädie der gesamten Medicinischen und Chirurgischen Praxis. Von Dr. G. J. Moser. 8vo. pp. 1138. Zweite stark vermehrte und verbesserte Auflage. Leipzig, 1837. London: A. Schloss.

This is a meritorious performance. The articles are judiciously selected, and contain a vast deal of practical information in small compass. We have perused with satisfaction and profit the article "Stricture," which, although not extending to ten pages, comprehends, nevertheless, every requisite information for the surgeon. We may add, that the "Encyklopädie" serves at the same time as a lexicon for the multifarious technical terms used by German medical writers.

TABLE,

Shewing the amount of Fees at different Schools, for unlimited Attendance on the Lectures required by the College of Surgeons and Society of Apothecaries; also the Fees for those Lectures only which are required by the above Corporate Bodies.

	Antony and Demonstra- tions.	Medicine.	Surgery.	Chemistry.	Materia Me- dica.	Midwifery.	Botany.	Forensic Me- dicine.	Additional percentages on those who have not a no- mination.	Matriculation Fee.	Total.	Total for the Lec- tures require by the College and Hall.

NEW GERMAN WORKS.

Analekten für Frauenkrankheiten von einem Vereine praktischer Aerzte. Bd. I. H. i. 8vo. pp. 160. Leipzig, 1837. Schloss.

Analekten der Chirurgie, unter Redaktion von Dr. E. BLASius und Dr. A. MosER. Bd. I. H. i. pp. 126. Berlin, 1837. Schloss.

THESE are congenerous works. Each professes to contain a collection of the principal monographs, prize-essays, and dissertations of recent date. The first part of the *Analekten* of Diseases of Women comprises memoirs on puerperal convulsions, phlegmasia alba dolens, leucorrhœa, &c. The surgical *Analekten* commence with Lisfranc's lectures on amputation of the cervix uteri, and extirpation of the uterus, together with Stromeyer's new treatment of club-foot.

Die Vergleichende Osteologie des Schläfenbeins. Von EDUARD HALLMAN, Mit. IV. Kupfertafeln, 4to. pp. 130. Hanover, 1837. London, A. Schloss.

THIS is an elaborate disquisition on the comparative osteology of the temporal bone. The author adopts the quadruple division of Cuvier in the order of investigation. 1. The squamous portion with the zygomatic process, which is never a separate piece. 2. The *os tympanicum*. 3. The *os petrosum*. 4. The *os mastoideum*.

Observationes Neurologicæ. Auctore FRIDERICO SCHLEMM. 4to. pp. 22. Berlin, 1834.

PROFESSOR SCHLEMM'S Dissertation treats of the minute anatomy of the medulla spinalis, the description of certain nervous filaments passing to the inferior rectus muscle of the eye, together with the dissection of the vidian and some of the ophthalmic nerves in the *Meleagris gallopavo*.

Encyclopädisches Wörterbuch der Medicinischen Wissenschaften. Herausgegeben, von Drs. Bsch, von GRAEF, HUFELAND, LANK, MÜLLER. Bd. xiv. H. 3 and 4. Berlin, 1836.

THE Berlin Cyclopedia of Practical Medicine continues to sustain its reputation. The articles "Ulcer" and "Poison," in the above volume, are elaborate and excellent.

LITERARY INTELLIGENCE.

In the press, an Inquiry into the Nature and Treatment of Cholera; being Part I, Vol. II., of an "Inquiry into the Principles and Practice of Medicine." By George Calvert Holland, M.D., Physician to the Sheffield General Dispensary.

Dr. Ayre of Hull has in the press a Letter addressed to the Rt. Hon. Lord John Russell, M.P., Her Majesty's Principal Secretary of State for the Home Department, on the Evil Policy of those Measures of Restorative Police and Quarantine, which are employed to arrest the progress of the Asiatic Cholera; with an Inquiry into the Nature of, and the means of obviating, those circumstances in the Physical Condition of the Labouring Poor which especially predispose them to the disease, and make them nearly the only victims of it.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

*At the Anatomical School, Kinnerton-Street,
near St George's Hospital,*

BY CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE II.

Internal mechanism of respiration—Form of the air-tubes and cells—Structure of the air-tubes—Cartilages—Mucous membrane—Longitudinal fibres—Circular fibres—Connecting and investing tissues of the lung—Blood-vessels of the lung—Chemistry of respiration—Changes of the air and of the blood—Physical cause of the change of colour of the blood—Adaptation of mechanism to chemical action—Ciliary motions of the bronchial mucous membrane.

BUT now let us proceed to examine the internal parts, to the functions of which the exterior motions of respiration, which we have been considering, are subservient.

Unless the air enter and pervade the lungs freely each time the chest is enlarged, and unless it find a ready egress from them as the chest is contracted, the external machinery, however perfect it may be, will work in vain. Now if we examine the structure of the lungs and their connected tubes, we shall find great cause to admire the beautiful provisions displayed in every part to prevent this want of harmony, and to facilitate and regulate the passage of air through them; and we shall meet with further illustrations of the nature of these

provisions in the modifications which disease can produce in them.

The lungs may be described as essentially constituted by the multiplied divisions of the expansible air tubes; and we shall obtain the best knowledge of their structure by tracing these tubes from the trachea to their terminations.

You must all be sufficiently familiar with the form and appearance of the windpipe and its larger branches. Their form and open calibre are given to them by their cartilages, which, in the trachea and the two first divisions, are in rings, almost surrounding the tube,—in the next order of bronchi, constituting irregular pieces; but at the origin of each branch still nearly annular, to keep open the orifice. These plates are fewer as the bronchi, on subdividing, become more slender, those at the orifices of branches being only half rings; and they cease altogether in the tubes of half a line in diameter, the tubes then being membranous to their terminations.

What are these terminations? Malpighi supposed the lungs to consist of a series of vesicles, freely communicating like those of sponge, and that in these the minuter bronchi terminate. Helvetius conceived that the vesicles of the lungs were only common cellular texture, filled with air, and forming spongy sheaths around the pulmonary blood-vessels, and freely communicating with each other. Haller, judging from the simple vesicular lungs of frogs, &c. came to nearly the same opinion. Even lately Magendie held the notion that the vesicular structure of each lobule was common, having free communication between its cells, besides through the bronchial tubes distributed through it; and a similar view seems to be entertained by Bourgery.

The researches of Reisseissen are the most complete and satisfactory of any that have been made, and I shall avail myself of some of his descriptions to convey to

you an idea of the minute anatomy of the lungs.

By various modes of injecting, he shewed that the bronchial tubes end in *culs de sac*, without mutual communication, except through the bronchi, and without communication with the interstitial cellular texture. Thus by inflating a minute bronchus, the cells of the portion of lung supplied by it became distended as regular roundish vesicles; and, by tying the bronchus, remained so, without any air passing to the adjoining cells. Mercury injected into a single bronchus gave the same result.

If, on the other hand, the common cellular texture be inflated through a minute cut in the pleura, the air is diffused in angular and irregularly-sized bubbles, giving inequality to the pleural surface, and appearing, as in the manner of a common emphysema, more between than in the lobules. Mercury poured into a bronchial tube, and allowed to run to its extremities, is seen in little globules under the pleura, communicating by branches at first very numerous and small, which again run into fewer and larger. If this be pressed between two glasses under the microscope, the mercury then goes to the extremities, and takes the regular cauliflower shape of the extreme canals.

Another mode adopted by Reisseisen to shew the shape of the minute extremities was this:—A portion of lung was kept some days in water, so that only very little air remained; hot water was then poured on it, which distended this air, and displayed the expansions of the terminal tubes like little bunches of buds or berries. [These appearances were exhibited in drawings.] I have repeated and verified these observations, and I think we may admit as correct Reisseisen's description of the form of the terminal bronchi.

Now, then, having considered the form, if we examine more minutely the component structures of the bronchial tree, from its trunk to these bud-like termini, we shall find that each is worthy of notice, and that there are some remarkable differences in the several parts. Thus we have seen that the cartilages—large and almost annular in the larger tubes, forming smaller and irregular segments in those of middle size, and ceasing almost entirely in the inner tubes—answer the important purpose of holding open the tubes in those parts where they are apt to be exposed to pressure. If the tubes were merely membranous, they might collapse together by atmospheric pressure, or by the distension of the pulmonary tissue at the upper parts of the lung, and be prevented from transmitting air to their extremities, whilst the absence of cartilage in the smaller tubes permits their flexibi-

lity and distension. Well, besides this cartilaginous frame-work, which varies according to the parts, we have at least three other structures, appearing in every part of the air-tubes.

1. A mucous membrane, with many muciparous crypts or follicles, conspicuous in the larger tubes, some of which penetrate through the other tunics, even to the cartilaginous coverings. In the smaller tubes this membrane becomes fine, thin, and destitute of distinct follicles, and in the terminal cells is of the greatest tenuity.

2. Longitudinal fibres, which are very elastic, like the elastic coat of the arteries. They are very conspicuous in the large and middle-sized bronchi, but they can be traced to the very ends of the tubes; it is these chiefly which cause the lungs to contract and collapse, when the chest is opened after death; and to a certain extent during life they must therefore assist in the act of expiration. Here you see them in the human bronchi [exhibiting a drawing], and here in those of the calf, in which they are more distinct and numerous than in man.

3. Circular muscular fibres, which are to be found in every part of the bronchial tree. In the larger tubes they are inserted into the ends of the annular cartilages, thus completing the rings. In the smaller they encircle the whole tube, some fibres being attached to the cartilaginous pieces, and to the longitudinal fibres, and some passing over them; and, by the aid of a lens, they can be seen, especially in the lungs of the lower animals, at the very extremities of the canals. The extreme bronchi have been shewn by experiment to contract during life, on the application of a mechanical or chemical irritant; and we shall soon find reason to suppose that their function renders expiration to a certain degree active. When we come to the pathology of asthma, we shall find other proofs of the irritable contractility of these bronchial muscles, and that their share in the process of respiration will serve to explain many facts which were inexplicable before the existence and action of these muscles were demonstrated. We shall recur to this subject when we come to the vital properties of the respiratory organs. The annexed drawing from the human subject exhibits a distinct view of the longitudinal, and of these circular or transverse fibres.

Thus, then, we have found in the respiratory apparatus a chest capable of enlargement and diminution; and within it not a mere bag, or assemblage of bags, but a series of elastic, expansible, and contractile tubes, subdividing into innumerable branches, each terminating in blind enlargements, and constituting the chief part of the parenchyma of the lungs. But this

FIG. 2.—Ultimate division of the Bronchi into clusters of air-cells. Magnified three diameters.

congeries of tubes and terminal cells is compacted together by other structures. There are the blood-vessels distributed over them, for the important purpose which we have afterwards to consider; there is an interstitial cellular texture, uniting the bunches of tubes and their vesicles into lobules, and in a more condensed form uniting these lobules into lobes; and there is an elastic serous membrane, a part of the bag which lines the whole chest, investing this congeries of

structures. This packs them into an organ with a simplicity of outward form which adapts it well to fill the changing capacity of the chest, while the mobility and elasticity of the connecting and investing structures still leave unimpaired the permeability and expansibility of each individual tube. Thus, when one part of the chest expands more than another, the air presses most directly through the tubes leading to that part, and an equality of pressure is thus kept up between the chest

and lungs, which is highly favourable to their harmonious working.

Although the elasticity of the bronchi gives the lungs a natural tendency in favour of contraction, so that, when not prevented by the pressure of air within, they collapse, yet the whole lungs will always *admit* of more distension than that which is required of them in respiration; so that if parts become obstructed, the air may enter more freely into other parts, for a short time without inconvenience; but, as we shall see hereafter, the continuance or excess of this partial distension is capable of producing permanent disease of a remarkable character.

Having thus sketched the route and the mechanism by which air passes to and fro in the lungs, the question, why does it so pass? brings us to another anatomical element to be considered—the blood-vessels, which are carefully and minutely distributed around the *air-tree*, especially its finer terminal parts. It is quite unnecessary for me to go here into any common details respecting the general circulation: I conclude *that* to be known; and I would reserve the particulars of the structure of the heart and great vessels, which deserve especial notice, to that part of the course in which their diseases will be considered. Blood of a dark hue is conveyed from the right ventricle of the heart through the pulmonary artery to the lungs, and it returns by the pulmonary veins into the left ventricle, of a florid red colour. Now by what ways does it pass as it undergoes this change? Minute anatomy has supplied us with an answer. It had long been known that fine injections would pass from the pulmonary artery to the pulmonary veins, or the converse, there being no valves in the veins of the lungs; but the actual communication of one with the other, through a set of capillaries on the sides of the minute air-tubes and cells, was first clearly demonstrated by Reisseissen. But it has since been seen in lungs of living frogs and other animals. In these drawings, which are enlarged from those of Reisseissen, you see this communication. In this, again, you see another set of vessels, the bronchial arteries, which are much smaller; they supply the mucous membrane and interlobular tissues, and may be seen here anastomosing with the pulmonary vessels. Branches from both bronchial and pulmonary arteries go to the pleura. The bronchial veins appear chiefly to empty themselves in the pulmonary veins.

The great object, then, of all the apparatus which has been occupying our attention, is that the blood and the air shall be continually moving in close proximity

to each other. We have said that the effect of this on the blood is to render it florid; and we may now add, that the chief effect on the air is to abstract a portion of its oxygen, and to substitute about an equal portion of carbonic acid gas. These are the fundamental facts of the *chemistry of respiration*. If we were to enter minutely into the details and explanations of these, we might be led into an interesting field of animal chemistry, which well might occupy half a dozen lectures; but we have so large a quantity of other matter more imperatively requiring attention, that we must dismiss the subject with a few cursory observations.

There are two views which have been taken of the use of the air which passes in and out of the lungs in respiration: one is, that its oxygen combines with, and carries off merely, a certain quantity of carbon, which the lungs are, by a vital secreting power, continually separating from the blood. A superfluity of this carbon is supposed to distinguish venous from arterial blood, it being acquired in the greater circulation through the system, as arterial is converted into venous blood, and thrown off by the pulmonary circulation, when venous blood is again made arterial. This supposes the air to be little more than a broom sweeping, or a current washing, away a carbonaceous excrement thrown out on the bronchial surface; and in confirmation, the black matter sometimes expectorated, and that almost always found in the bronchial glands and other corners of the lungs, have been adduced as instances where the air had not swept or washed clean. But there are many, and some I think conclusive, objections against this view. It is opposed by the chemical fact, that simple carbon, were it so excreted, could not combine with oxygen at the temperature of the lungs. It is also opposed by the fact, that the simple contact of air with the blood, without any structure to separate the carbon from the latter, is sufficient to effect the same change in the blood and in the air, as that which takes place in the lungs. Moreover, it is found that not only is no secreting structure necessary, but the change takes place in spite of an intervening membrane, such as a bladder, gold-beaters' skin, or even a thin lamina of Indian rubber. These and many other facts are quite inconsistent with the supposition that carbon is first separated from the blood, and then united with the oxygen of the air.

Of the black pulmonary matter we may find a sufficient source in the blacks and soot from our candles and fires, of the abundant presence of which in the air which we breathe, our linen, our ceilings, and every thing white that is exposed to

it, afford sufficient evidence. The lungs act as a filter for these impurities contained in the air, which, being insoluble, are not absorbed away, but accumulate in the tissue where they have become entangled.

The other view of the chemistry of respiration is, that the oxygen which is missing in respired air is absorbed into the blood, which throws out at the same time about an equal quantity of carbonic acid gas. The blood is thus arterialized, and, by the oxygen which it contains, rendered fit to excite and nourish the tissues, of which it is the proper pabulum; but in this office, under the control of an unknown vital influence, the oxygen exerts its chemical affinity, and abstracting from the blood a certain quantity of carbon, becomes carbonic acid; and the blood is thus again changed from arterial to venous. The chief characteristic, therefore, of arterial blood is, that it has *oxygen*,—of venous blood, that it has *carbonic acid*, combined with it; and the substitution of one principle for the other will effect the conversion of one kind into the other. This view is supported by a great many remarkable facts, and I know of none which really opposes it.

The change of blood in the lungs is essentially a chemical process, to promote which the mechanism of respiration is eminently adapted; but we find the same change to take place out of the body, and to be influenced as chemical processes generally are. The change of the blood in the greater circulation, from arterial to venous, is also partly chemical; and the affinity which we have adverted to, of oxygen for carbon, is a chemical force that is no doubt active, but this is probably greatly under the control of the vital powers; and I hold it to be a beautiful proof of the useful subserviency of inorganic to vital chemistry, that this affinity, which we know to be merely chemical, must tend to promote the formation of urea, uric acid, ammonia, gelatine, and other matters containing less carbon than the principles of the blood from which they are formed, which are more properly the products of vital organs, and the necessity of whose generation in the healthy state is obvious from the constancy and regularity with which it is carried on. We have no time to trace further the interesting relations that thus declare themselves in the chemical and vital laboratory of the body; but I would point out, as one pretty obvious corollary from them, that the function of the lungs stands in a relation peculiarly close with those of the great secreting organs of the body—the kidneys and the liver.

We cannot enter on the subject of the

composition of the blood; but I would call your attention to the remarkable physical difference which we have already noticed between venous and arterial blood—that of colour: that of venous is the most intense dark red—so dark that to reflected light it is almost black; but by transmitted light, it is of the finest crimson. Arterial blood, on the other hand, is of a bright crimson by reflected light; but it is of a dingier colour and more opaque than venous blood by transmitted light. This fact led me to the suspicion that the apparent brightness of arterial blood might be owing to the production of a white opacity in it, which would have the effect of reflecting white light through a thin film of the deep crimson. On closely examining the change of colour, whether produced by air or by the addition of saline matter, I have found that a certain white opacity always accompanies the brightening of blood: thus, if you closely watch this coagulum of dark blood when I drop it into this saline solution, you will see that it becomes first white and opaque at the edges; and this whiteness extending into the mass, shines through the deep crimson colouring matter, and gives it the florid hue. A thin drop of dark blood on a glass, viewed with a lens, appears transparent at first, but gradually as the air begins to act on it, or instantaneously on the addition of a grain of salt, a cloud of opacity is seen in it, which, when seen by reflected light, gives the florid colour of arterial blood. Seen through a good microscope, this opacity is observed to be caused by a myriad of distinct globules, smaller than those of the blood, apparently of the size of the central globule, and of those seen in serum. I have arranged this microscope that you may see this after lecture. The oxygen of the air, or the salt, appears to have the power of giving density or distinctness to the white organic particles contained in the blood, or even to increase the number of them; and these particles, acting as so many little mirrors, which reflect light through the colouring matter, give it the brightness so characteristic of arterial blood. Thus the change of colour appears in a simpler light, and one less calculated to mislead, because we are thus reminded of other changes in condition which accompany it. I should not have introduced this matter, but that it serves to show the utility of bringing all our senses to bear on the investigation of a subject—a leading principle in these lectures.

To return to the office of the lungs:—we have no evidence that there is any apparatus organized peculiarly for the absorption of oxygen into the blood, or the exhalation of carbonic acid from it. We

have noticed that the displacement of carbonic acid by oxygen takes place in blood out of the body; that the intervention of a membrane does not impede it; and it becomes a matter of obvious inference, that the distribution of the blood in millions of capillaries around the air-cells and tubes, with the thinnest possible membranes only separating it from the air, is only an admirable mechanical contrivance for rendering the chemical action between the air and the blood as complete as possible. The fact that air can pervade a membrane was long doubted; and this doubt was considered, by a great many writers, a sufficient reason for rejecting the view which we are considering; but this doubt was not well founded; the facts described by Priestley and John Hunter being enough to remove it. These found that venous blood became florid, although contained in a bladder or goldbeater's skin; and Goodwyn rendered the blood in the jugular vein of a living rabbit florid by blowing on it. I had the satisfaction of setting this question still further at rest, by showing, many years ago, that not only was the blood changed in colour, but that the air received carbonic acid from it, and consequently, that the air must have exerted an action on the blood through the membrane. Since I made this experiment, the researches of Dutrochet and Mitchell have developed the fact of the passage of gases or liquids through membranes into a general principle: and one which I believe may be referred to a still simpler law, that of the intermixture of different gases, as developed by Dalton and Graham, and which depends on the comparative elasticities of different kinds of matter. All these steps in science, which we cannot dwell on longer, have dispelled many difficulties which used to beset the theory of respiration: and the further results obtained in the experiments of Edwards, that azote, as well as oxygen, is sometimes *absorbed*, especially during the winter, and sometimes *exhaled*, leave no doubt that gases, as well as liquids and solids, may combine with, and be separated from, the components of the body.

A few other points of adaptation of the minute structure of the lungs to promote the chemical action between the air and the blood, are worthy of notice. The air-canal is lined throughout with a mucous membrane. This, in the trachea and larger bronchi, is not only of a considerable thickness, but is furnished with numerous distinct follicles, which throw out abundance of the peculiar slimy albuminous secretion called mucus. In the smallest bronchi these follicles cannot be detected, and it is uncertain whether they exist; but the membrane is every where moist

and slippery, as if covered by a thinner mucus of the same kind. The utility of this secretion is obvious, in protecting the membranes and tissues of the interior from divers irritations of extraneous matter, from excessive dryness, cold, or heat of the inhaled air; and hence the need of its being thicker and more abundant at the commencement of the canal, where these irritations would exert their fullest effect. But I believe this mucus, in the finer tubes and their extremities, to be useful in another way, in promoting, by its chemical quality, the transfer of oxygen from the air to the blood. Fourcroy long ago shewed that the bronchial mucus had, in a signal degree, the property of absorbing oxygen and of yielding it again to other substances, such as metals; hence it is the most effectual medium for killing mercury. I think, therefore, that it is reasonable to suppose the mucus with which the bronchi are bedewed, to aid in facilitating the oxygenation of the blood. A remarkable phenomenon has been lately observed with regard to the mucous membrane of the bronchial tubes of animals recently killed. When it is examined under water, through a microscope, the water is seen to be thrown into distinct and very rapid vortices or currents, which continue with great vivacity for a considerable time, even after the membrane is quite cold. These currents were ascribed by their discoverers, M. Purkinjie and Valentin, to the movements of very fine hairs, or *cilia*; and as they are seen in the gills of some aquatic animals, as the common muscle, in which they obviously serve the purpose of respiration, by keeping up a fresh supply of water to the branchial vessels, they suspected them to exert some similar effect on the air in the bronchial surface of the mammalia. But Dr. Alison has well remarked, that as the same currents are to be seen also in the mucous membranes of the genital organs of female animals, it is more reasonable to suppose, that the object of the movements that produce them is rather the equal diffusion of the mucus, the uniformity of which may be essential to the effectual performance of the functions of these organs. The same distinguished physiologist considers the opinion of Purkinjie and Valentin, that these currents are produced by cilia in motion, as too hastily assumed, their existence in the air tubes having never been proved; and he is inclined rather to ascribe them to a vital attraction and repulsion—a principle the existence of which he has brought many ingenious arguments to prove, and one which, if it do obtain, must have a large share in the motions and functions of the body.

ON THE HUMAN VOICE.

By PROFESSOR MÜLLER.

WE never remember to have read a more happy application of the laws of mechanical science to the structure and physiology of living bodies, than that which Professor Müller has effected in the account which he has given in the Third Part of his "*Physiologie des Menschen*" of the larynx and voice. He has detailed them there at too great length to admit of our translating the whole section of the work, though it would fully deserve it, could we spare room for it; but we shall endeavour, in as brief an abstract as possible, to give the most important results which he has arrived at, cleared of all the technicalities of music and mechanics, which can be spared, without rendering the description unintelligible.

The following are the proofs which he adduces, independently of those drawn from his experiments, of the glottis being that part of the vocal tube by which the voice is produced:—1st. That when an opening is made in the trachea below the glottis, the voice ceases and returns when that opening is closed—while an opening made above the glottis does not necessarily destroy the voice. 2nd. Magendie's experiments, showing that the voice continues when the epiglottis, superior vocal (or false) ligaments, and the top of the arytenoid cartilages have been removed. 3rd. The visible vibration of the inferior vocal ligaments, when the voice is heard, in animals whose glottis is exposed, and in men who have attempted suicide. 4th. The injury of the laryngeal nerves, which supply the small muscles acting on and modifying the aperture of the glottis. 5th. The possibility of producing sounds similar to those of the human voice, by blowing through the larynx when removed from the body, when the vocal ligaments have a certain degree of tension, and the glottis is open to a certain width, and this, when every other part, except the inferior vocal ligaments and their attachments, is cut away. Hence the glottis and its immediate limits, the inferior vocal ligaments, may be regarded as the essential vocal apparatus—the trachea and bronchi being analogous to the conducting pipe, or, as organ-builders call it, the boot of the pipe—and all the apparatus above the inferior vocal ligaments to the body or bell of wind instrument or organ pipes, by which the sound produced in the glottis, or by the vibrating tongue, is modified. In birds

there is a different arrangement of similar structures; the organ producing the voice is the inferior larynx, which is at the division of the trachea, and to which the bronchi serve as the conducting pipe, while the trachea, and the upper larynx which has no ligaments, perform the office of the pipe which modifies the sound produced at the lower larynx.

The vocal ligaments are rendered capable of regular vibrations, like those of membranes stretched at both ends, by being composed of the same peculiarly elastic tissue as has been pointed out by Lauth, Schwann, and Eulenbergh, as existing in the middle coats of arteries—the ligamentum nuchæ—lig. flava of the vertebral laminae—stylo-hyoid ligament—longitudinal elastic fibres of the trachea and bronchi, and many other parts of the body of man and animals. It is characterized by its yellowness, dryness, slight vascularity, and by its frequently giving off from the larger bundles, of which its fibres are composed, very fine branches, which, anastomosing with those from adjacent bundles, often form a kind of network. In chemical composition it is principally distinguished from the other fibrous, tendon-like or ligamentous tissues, by the difficulty with which gelatine can be obtained from it—and in physical characters, it is most marked by its extreme elasticity, which is permanent in it under almost all circumstances, even after it has been preserved for many years in spirit. But the vocal ligaments are not the only parts of the larynx in which it exists; the thyrohyoid and middle crico-thyroid consists of it, and it is extensively distributed through the whole interior of the organ, arising principally from the inferior half of the angle of the thyroid cartilage, and thence radiating in fibres backwards, downwards, and a little upwards, forming a continuous membrane attached to the whole of the upper edge of the cricoid cartilage (except where the arytenoid cartilages play), and to the anterior angle and edge of the bases of the arytenoid cartilages. A somewhat increased thickness of this membrane at three parts forms the so-called middle crico-thyroid, and the inferior thyro-arytenoid ligaments; it forms the upper vocal ligaments, which are also connected to the lower by a thin layer of elastic tissue lining the venticulum Morgagni. The same tissue is found also in the lateral hyo-thyroid, thyro-epiglottic, and glosso-epiglottic ligaments; and if to these be added the longitudinal fibres of it in the membranous part of the trachea and bronchi, an idea may be formed of the great extent of walls fitted for vibrations

and resonance in the neighbourhood of the vocal organ.

The vocal ligaments are made to possess various degrees of tension, by the contraction of the several muscles acting on the cartilages to which they are affixed. Thus the crico-thyroid, drawing the thyroid nearer to the cricoid cartilage, increase their tension, while the arytenoid cartilages are fixed; and the posterior crico-arytenoid muscles effect the same change if the thyroid cartilage be fixed, and the arytenoid cartilages be coincidentally approximated by the proper arytenoid muscles. According to the degree of tension produced by these muscles, the glottis becomes longer or shorter. It is made narrower by the approximation of the arytenoid cartilages by the proper arytenoid muscles, and wider by the separation of these cartilages by the posterior crico-arytenoid muscles.

The elasticity of the ligaments connecting these cartilages will maintain the corresponding edges of the thyroid and cricoid cartilages in approximation, without the aid of muscular effort; so that while the arytenoid cartilages are fixed, there will always be a certain degree of tension of the vocal ligaments; and when the posterior crico-arytenoid muscles act, to draw the arytenoid cartilages backwards, they must have this elastic middle crico-thyroid ligament to act against.

The glottis is capable of receiving the following forms:—When at rest it is lanceolate, growing wider on inspiration, and narrower on expiration. Its sides are formed behind by the inner surfaces and anterior processes of the bases of the arytenoid cartilages; before, and to the greatest extent by the vocal ligaments, attached to those processes, and the angle of the thyroid cartilage. When at its greatest width, it has the form of a lozenge, with its posterior angle cut off, and the distance between the lateral angles, at which are the anterior processes of the arytenoid cartilages, may be $5\frac{1}{2}$ lines. In its narrowed condition the glottis may have a triangular form; it may be open in its whole length, the arytenoid cartilages being merely approximated; or by their coming in contact at their anterior angles, a double aperture may be produced; or by their coming completely in contact, the posterior part of the glottis may be entirely closed, and there will then be no opening except that between the vocal ligaments. This last condition is produced by the united action of the lateral crico-arytenoid and the proper arytenoid muscles; the aperture will be pointed both before and behind, and will vary in width according

to the coincident degree of tension of the vocal ligaments.

The loosening and shortening of the vocal ligaments is effected by the thyro-arytenoid muscles, which at the same time narrow the space above and below the lower vocal ligaments.

The exact form of the glottis during the emission of sound is not precisely known, but it is certainly very much narrowed, as is shown by Mayo's observations on those who had attempted suicide, Rudolphi's in a case of loss of the nose and palate, and Magendie's on living animals. Müller thinks, in accordance with the opinions of the last-mentioned physiologist, that the posterior part of the glottis, between the arytenoid cartilages, is generally closed during the production of voice, but as in the dead larynx he does not find this a necessary condition, he does not so decide it.

The following is the mode employed by Müller in experimenting on the production of voice with the larynx after it is removed from the body. The principal objects to be attained are, a fixed position of certain of the cartilages, and at the same time a regular and measurable power of moving others, so as to give the vocal ligaments the desired degrees of tension and varied forms. These he attains by laying the larynx with its posterior wall on a board, and there fixing it firmly by the cricoid cartilage; the arytenoid cartilages are then fixed by an awl or metal pin, run transversely through them both, near their bases. This is the most delicate part of the process, requiring great care, in order that when the extending force is afterwards applied, both vocal ligaments may be made equally tense; and so that when these cartilages are pressed towards each other on the pin, their anterior or vocal processes may touch. The transfixing pin may then be fixed with cords to the board. When this has been accomplished, and the cricoid and arytenoid cartilages are both fixed to the board, any degree of tension may be given to the vocal ligaments by drawing the angle of the thyroid cartilage forward. This is best done, and will admit of being measured, if a fine string be affixed to it just before the insertion of the ligament, then passed over a pulley, and then have hung on at its opposite end one of a pair of delicate scales, which may be loaded with different weights, so as to draw away the anterior part of the thyroid from the arytenoid and cricoid cartilages, as much as the vocal ligaments will allow. In proportion as the weight is increased, the vocal ligaments will now be stretched. All the parts of the larynx above the lower vocal ligaments may now be cut away, as they are unnecessary for the

production of the required sound, and the actions of the ligaments may be better observed when they are removed. A wooden tube to blow through is put into the end of trachea.

The following facts have been observed in the frequent performance of experiments on larynges, thus prepared.

On blowing through the trachea when the glottis is narrow, the vocal ligaments give out full and clear notes, which come very near to those of the human voice, and much resemble those produced by blowing over moist elastic arterial coat, stretched over the end of a tube, as in the best kind of artificial larynx. They differ from those obtained when the ventricle, upper ligament, &c. are affixed, only in being less loud. The vocal ligaments sound best and most easily when the posterior part of the glottis, between the arytenoid cartilages, is closed, though this form is not absolutely necessary; and if the tension of the ligaments be the same in both cases, the note produced is of the same height, whether the posterior part of the glottis be open or not, which is at once an evident proof that it is the vocal ligaments whose vibrations produce the sound, and that the air is not the primary vibrator, for in that case the note would be deeper when the glottis was open to its whole length than when it was open only for the length of the vocal ligaments. And if the anterior angles of the arytenoid cartilages touch, so that there is an aperture both behind and before them, no second note is produced by the second posterior aperture, though the air sometimes rustles, in passing between the cartilages and their uniting membrane.

If the ligaments be equally tense in all cases, the width of the aperture of the glottis does not make any difference in the height of the note produced,—it is only less clear, in consequence of the noise of the air rushing through, when there is a wide opening; and in this, as in many other respects, a larynx exactly resembles the artificial ones made with bands of caoutchouc and instruments with membranous and metallic tongues, in which a wider opening only alters the expression, and not the height, of the note.

If the vocal ligaments be unequally tense, there are rarely two notes produced; but when the tension is equal, there is occasionally produced a much higher note than the proper one, from the ligaments coming in contact in some part of their length. Notes can as well be produced when the ligaments touch each other every where, as when they have a narrow opening between them; and if the tension be the same, the notes produced in these

two conditions are not different as regards their height. In these cases the notes are produced most easily when the ligaments which are in contact are very lax, and they are caused by the interrupted passage of air through them, and may be well produced when the glottis is extremely short.

Low notes may be produced in a very short as well as in a very long glottis, and high notes in a very long as well as in a very short one: if only in the short one for low notes the ligaments are very lax, and touch each other; and if in the long glottis for high notes, the ligaments are at the same time very tense. This shortening and lengthening of the glottis, without alteration of its tension, may best be effected by compressing the lips of the glottis with forceps; while the degrees of tension may be altered by pressing the angle of the thyroid cartilage backwards to the cricoid.

When the whole vocal ligaments, from the angle of the thyroid cartilage to the vocal processes of the arytenoid cartilages (in contact with each other), are in vibration without touching, the notes produced by increasing degrees of tension of the ligaments do not increase in height in precisely the same degrees as those produced by strings and membranes stretched at both ends; there are always some half or whole notes below those given by strings and membranes. For example: with the same length of string, the notes or numbers of vibrations increase directly as the square roots of the powers producing the tension; i. e. if a string, extended by a weight of 4, give the note *c*, it will give the octave or *c'* when extended by a weight of 16, and the second octave or *c''* with a weight of 64. But by adding weights into the scale attached to the thyroid cartilage, as above described, according to this rate of increase, octaves are not obtained from the vocal ligaments, but notes, $\frac{1}{2}$ a note, or $1\frac{1}{2}$, 2, or 3 whole notes below the octaves. However, the analogy is near enough to show that the notes of the human vocal organ, so far as they are produced by the glottis and its limits, are analogous to those of strings and membranous tongues. [The experiments proving this are of very great difficulty, and require considerable practice to perform them correctly, but we cannot undertake to translate the whole of Müller's long directions.]

The following are the results of some of his successful attempts. The degrees of tension were always increased from 4 to 16, and from 16 to 64; and the weights thus employed were *l. oz.*, each about equal to a half ounce in this country.

Weights in Loths.			
Tension .. 4		16	64
1st Experiment.—Notes	<i>c'</i>	<i>a'</i>	<i>g''</i> sharp.
2d do. do.	<i>c'</i> sharp	<i>b'</i>	<i>a''</i> sharp— <i>a''</i>
3d do. do.	<i>g'</i> sharp	<i>c''</i> sharp	<i>c'''</i>
4th do. do.	<i>a'</i>	<i>d''</i>	<i>c'''</i>
5th do. do.	<i>a</i> sharp	<i>f'</i> sharp	<i>g''</i>
6th do. do.	<i>a</i> sharp	<i>g'</i> sharp	<i>g''</i>
7th do. do.	<i>d'</i>	<i>c''</i>	<i>a''</i>
8th do. do.	<i>d'</i> sharp	<i>b'</i>	<i>a''</i>
9th do. do.	<i>g</i>	<i>g'</i>	<i>g''</i>

The two octaves impure.

The notes may be in every case determined by a well-tuned piano, struck by a second person.

The vocal ligaments, separated from the larynx and stretched, act nearly like strings. Thus one gave, with a weight of 16, *a* sharp. When the weight was reduced to 4, it gave *d*; and when it was increased to 16, it gave *a* sharp again.

By altering the tension in the same direction, the notes of the larynx may pass through a compass of two octaves; with greater tension, disagreeable, higher, whistling or shrieking notes are produced. If the experiment shewing this cannot be well performed by increasing the weight, and drawing over the pulley in the direction of the ligaments, it may be done by making a lever of the thyroid cartilage, and drawing it downwards, by a weight attached to a cord, towards the cricoid, in imitation of the action of the crico-thyroid muscles, which act thus in the production of high notes during life, by diminishing the breadth of the crico-thyroid ligament. The following results were obtained by this plan, in two succeeding experiments on the same larynx:—

Experiment I.

Weights.	Notes.
$\frac{1}{2}$ loth	<i>a</i> sharp.
1 —	<i>b</i>
$1\frac{1}{2}$ —	<i>c'</i>
2 —	<i>c'</i> sharp.
$2\frac{1}{2}$ —	<i>d'</i>
$2\frac{8}{10}$ —	<i>d'</i> sharp.
3 —	<i>e'</i>
$3\frac{1}{2}$ —	<i>f'</i>
4 —	<i>f'</i> sharp.
$4\frac{1}{2}$ —	<i>g'</i>
5 —	<i>g'</i> sharp.
$5\frac{1}{2}$ —	<i>a'</i>
6 —	<i>a'</i> sharp.
$6\frac{1}{2}$ —	<i>b'</i>
7 —	<i>b'</i> — <i>c''</i>
$7\frac{1}{2}$ —	<i>c''</i>
8 —	<i>c''</i> sharp.
$8\frac{1}{2}$ —	<i>d''</i>

Weights.	Notes.
$9\frac{7}{10}$ loths	<i>d''</i> sharp.
$10\frac{7}{10}$ —	<i>e''</i>
$11\frac{7}{10}$ —	<i>f''</i>
13 —	<i>f''</i> sharp.
15 —	<i>g''</i>
17 —	<i>g''</i> sharp.
19 —	<i>a''</i>
22 —	<i>a''</i> sharp.
25 —	<i>b''</i>
28 —	<i>c'''</i>
31 —	<i>c'''</i> sharp.
35 —	<i>d'''</i>
37 —	<i>d'''</i> sharp.

No higher note.

Experiment II.

Weights.	Notes.
$\frac{1}{2}$ loth	<i>b</i>
1 —	<i>c'</i>
$1\frac{1}{2}$ —	<i>c'</i> sharp.
2 —	<i>d'</i>
$2\frac{1}{2}$ —	<i>d'</i> sharp.
3 —	<i>e'</i>
$3\frac{1}{2}$ —	<i>f'</i>
4 —	<i>f'</i> sharp.
$4\frac{1}{2}$ —	<i>g'</i> +
5 —	<i>g'</i> sharp.
$5\frac{1}{2}$ —	<i>a'</i>
6 —	<i>a'</i> sharp.
$6\frac{1}{2}$ —	<i>b'</i>
$7\frac{1}{2}$ —	<i>c''</i>
$8\frac{3}{10}$ —	<i>c''</i> sharp.
9 —	<i>d''</i>
10 —	<i>d''</i> sharp.
11 —	<i>e''</i>
12 —	<i>f''</i>
13 —	<i>f''</i> sharp.
15 —	<i>g''</i>
$17\frac{1}{2}$ —	<i>g''</i> sharp.
18 —	<i>a''</i>
20 —	<i>a''</i> sharp.
22 —	<i>b''</i>
26 —	<i>c'''</i>
29 —	<i>c'''</i> sharp.
32 —	<i>d'''</i>
37 —	<i>d'''</i> sharp.

No higher note.

After the first experiment, the vocal ligaments had only altered so much as to give *b* instead of *a* sharp with a weight of a quarter of an ounce. From these experiments it follows, that about a pound of muscular power may produce the notes within the compass of two octaves.

But still lower notes may be produced if the vocal ligaments be freed from every degree of extension exercised by the middle crico-thyroid ligament, and allowed to have the greatest laxity possible, by drawing the thyroid cartilage towards the arytenoid by a cord running over a pulley behind the larynx, with weights attached, as before, to it. In this method, and by blowing upwards through a larynx, Müller obtained, by gradually increasing the weight, almost a complete scale downwards, from *d'* sharp to *B*. In leaving the ligaments thus free from the action of the crico-thyroid ligament, and other parts, while the posterior part of the glottis is closed, the action of the thyro-arytenoid muscle is imitated, in the shortening and relaxation of the vocal ligaments.

[To be continued.]

OBSERVATIONS
ON THE
REACTION OF THE SALIVA UPON
RED AND BLUE LITMUS, AND
TURMERIC PAPER.

To the Editor of the Medical Gazette.

SIR,

A PAPER on some physiological and pathological properties of the saliva, by M. Donné, appeared in the *Archives Générales* of May and June, 1835. M. Donné showed, that by comparing the morbid with the healthy state of this fluid, we may distinguish accurately between inflammatory and non-inflammatory affections of the stomach. He asserts, that on no occasion has he found the saliva acid when the appetite and digestion were good; and states, that acidity of the saliva is a diagnostic symptom of gastritic irritation.

I have misplaced a reference to a French writer who makes a similar assertion respecting the sputa in chronic bronchitis, and states, that by this means it may be distinguished from phthisis, in which the sputa are alkaline.

I have occasionally tested the truth of these observations, and have found the sputa neutral in phthisis. In a fatal case of chronic bronchitis (ascertained to be this disease on dissection,) I found the sputa, at various periods, to be alkaline, acid, and neutral.

From a few desultory observations, I was led to doubt the accuracy of M. Donné's conclusions; finding, however, that that gentleman has the reputation of being a talented and industrious observer, I determined upon a closer line of investigation. The practice of the York Hospital presents but cases of unquestionable gastritis, and I therefore turned my attention to the state of the saliva generally. The observations I made I have subjoined in the form of tables. Their unexpected result has induced me to publish them, hoping the conclusion to which they may lead may attract the notice of M. Donné, and of other inquirers into the pathological states of the fluids of the body. Pathological chemistry will soon rival pathological anatomy in importance.

I made these observations indiscriminately upon forty-eight in-patients of this hospital: of this number there were not three cases alike: it comprised diseased joints in every stage, ulcers, accidents, and the various other diseases usually found in a general hospital. Thirty-six, or three-fourths of the whole number, asserted that they had a good appetite and digestion. This number included the most varied cases: ulcers on the legs, with and without impaired health; diseased hip joint with sinuses, emaciation and diarrhoea; senile gangrene; schirrous uterus, &c. Eight had appetite and digestion more or less impaired; of these, two were under the influence of mercury: four had loss of appetite, or frequent vomiting.

The diet of these individuals was various: a few were on fever and full diet, but the majority on house diet, consisting of beef or mutton, and baked flour or rice puddings, on alternate days, for dinner; and tea, milk, or broth, for breakfast and supper. The latter was taken at half-past five; dinner at half-past twelve; and breakfast at half-past eight. With a few exceptions, no individual took medicine after his meal until I had made the observations.—Slips of paper, an inch and a quarter

in length and a third of an inch in breadth, were used. In the first nine series, litmus and turmeric paper were used, on Sept. 13th (evening.) Litmus paper, reddened with dilute acetic acid, was substituted for the turmeric: in the remainder it was reddened with very dilute sulphuric acid; thirty minims of the official dilute acid being mixed with four ounces of distilled water for this purpose.

The papers were sometimes put into the mouth at the same moment, one being inserted at each end; but generally in succession, with an interval of from one to three or four minutes. The reaction was noted down, as was also the state of the tongue, at the moment of withdrawal. Care was taken that the papers were well moistened.

The whole of the observations, with the exception of those in the two last series, were made at from half-past eight

to nine o'clock in the evening, and from ten to half-past ten in the morning.

Every shade of tint was observed, as will appear from the tables. *Strongly acid* means, that the litmus was immediately and deeply reddened: *acid*, that the reaction was immediate and distinct, but in a less degree; and so on with the others. *Very slightly acid*, and *very slightly alkaline*, express changes not easily perceptible, and which I noted, solely that the observations might be more exact.

The tongue was noted as being *white* when it was of a greyish, milk-like colour, but not coated, and was sometimes moist and sometimes rather dry. The tongue was said to be pale when of a whitish red colour, *smooth* and moist; a state observed most frequently in relaxed habits. The other states mentioned, include various degrees of each, under the same name.

A TABLE of 567 Observations on the Action of the Saliva upon Red and Blue Litmus and Turmeric Paper, and on the corresponding Appearances of the Tongue.

Tongue having a white fur, dotted with red points	Morning ..	0	0	1	5	9	0	0	0	2	17
	Evening ..	1	1	5	3	4	0	0	0	0	14
Total of evening observations, including Sept. 6th		30	49	52	34	42	2	3	4	0	216
Total of morning observations ..		10	32	46	40	148	6	21	27	21	351
Total of both		40	81	98	74	190	8	24	31	21	567

I would remark, that the three central degrees of reaction are very nearly allied. The same remark is applicable to the observations in the three columns

to the right and left. It will be instructive to throw these together under the heads of acid, neutral, and alkaline, as follows:—

	Acid.	Neutral.	Alkaline.	Total.
Morning observations	88	194	69	351
Evening observations.....	131	78	7	216

What conclusions, then, must be drawn from the preceding tables? The following appear to me correct:—

1. The saliva may be acid without any apparent disease of the stomach, and when the individual is in good health.

2. It is alkaline during different degrees of gastric derangement, as indicated by the tongue.

3. It may be alkaline, acid, and neutral, when the gastric phenomena are the same; and, consequently, acidity of the saliva is not a diagnostic mark of gastritic derangement.

4. In general it is alkaline in the morning, and acid in the evening.

The fourth conclusion will require some explanation, since it is obviously contrary to the earlier series, although in accordance with the general results. It must, however, be remembered, that the alkalinity of the saliva was tested, in the first nine series, by turmeric pa-

per, which is not a sufficiently delicate re-agent for the purpose. The consequence would be to place those in which the saliva was alkaline, under the head of neutral; leaving the results obtained by means of the litmus unaffected. Therefore we find, that on the five first mornings (on which the turmeric paper was used) of 196 observations, the saliva was neutral in 99, and alkaline in *one* only; whereas on the succeeding mornings (red litmus being used), of 156 observations, it was alkaline in *seventy-three*, and neutral in *fifty-nine* only.

It may be also remarked, as opposed to this conclusion, that in the first five morning observations, of the gross number 196, the saliva exhibited various degrees of acidity in *ninety-six*; while, in the succeeding morning observations, this was observed in *thirty-two* only of 156.

I cannot explain these discrepancies,

except by supposing that during the first experiments, the novelty of the procedure and the evident expectation of tasting something, on the introduction of the test-papers into the mouth, caused the saliva to be temporarily acid;—a supposition in accordance with our knowledge of the influence of mental emotions on the secretions in general.

The uniformity in the evening observations is at least curious, and appears to me highly corroborative of the truth of the fourth conclusion.

Assuming as a general fact, then, that the saliva is acid in the evening and alkaline in the morning, it remains to inquire under what circumstances it varies from these states.

From the few observations I have made, it is not improbable that the acidity of the morning saliva is a symptom of disease, but not exclusively of the gastritic form. I subjoin a few cases selected from the mass:—

1. Reuben Jones, aged 30, admitted suffering from retention of urine. He has a stricture of the urethra, which admits only the smallest bougie. General health good. Tongue natural.

2. William Walker, aged 60, complained of difficulty of breathing, sleeplessness, frequent micturition, and pain about the rectum and perineum. He has a large calculus in the bladder*. Appetite unimpaired; tongue white. Has gruel diet, and takes an opiate at night. Pulse regular.

3. John Bowes, aged 21, suffers from disease of the hip-joint; sinuses run into it, and discharges profusely. He is emaciated, and suffers occasionally from diarrhœa, which is kept in check by Dover's powder combined with mercury and chalk, at bed-time. Appetite good; tongue pale; pulse quick.

4. Fanny Tate, aged 30, has serofulous abscesses in the neck, and severe neuralgic pains of the occiput and temples. Countenance sallow and anxious; movements languid; appetite somewhat impaired; tongue pale; pulse regular.

5. Thomas Ruddock, aged —, has abscess in the left knee-joint, following an injury. Is sleepless and feverish; pulse excited; appetite somewhat impaired; tongue furred.

6. John Porteus, aged 63, had his leg amputated below the knee ten days ago, (August 27th.) for ulceration of the cartilages of the ankle-joint. He is emaciated, his constitution is impaired, and he has occasional diarrhœa. Pulse rapid; tongue with a white coat and a few prominent papillæ. The stump healed by the first intention.

7. George Shepherd, aged 63, has languid ulcers on the legs; is pale and weak; and vomits almost every thing he takes. No tenderness of epigastrium; tongue thickly coated.

I subjoin a table of the observations made upon the saliva of these patients:—

		Acid.	Alkaline.	Neutral.
Jones	{ Morning	4	0	0
	{ Evening	3	0	0
Walker ..	{ Morning	7	2	0
	{ Evening	7	0	0
Bowes ..	{ Morning	6	2	0
	{ Evening	3	0	0
Tate	{ Morning	4	2	3
	{ Evening	4	0	1

* Mr. Champney performed the operation of lithotomy upon this patient on the 20th Sept. and removed a large stone, shaped like an equila-

teral triangle, having uric acid nuclei and a phosphatic crust. The patient is doing well.

		Acid.	Alkaline.	Neutral.
Ruddock.	{ Morning	3	2	4
	{ Evening	5	0	0
Portens ..	{ Morning	6	0	3
	{ Evening	4	0	1
Shepherd	{ Morning	7	2	0
	{ Evening	7	0	0

The state of the atmosphere seemed to influence the re-action of the saliva.

Should any of your readers be inclined to prosecute these researches, I would just remark, by way of caution, that the changes in the colour of the papers should be noted immediately, as an evident tendency to acidity is very soon observed. I took particular care to notice this, and found that in 308 of my observations, at the end of six hours the colour of the paper was unchanged after the first action of the saliva; in 250 there was an evident tendency to acidity; alkaline becoming neutral—neutral, acid—and acid, strongly acid; while in nine only was there a reverse tendency.

These observations plainly lead to conclusions opposed to those of M. Donné. If his inquiries have been made principally with the morning saliva (which is very probable), the conflicting statements may, in some degree, be harmonized.—I am, sir,

Your obedient servant,

T. LAVCOCK,
House Surgeon, &c.

York County Hospital,
Sept. 25, 1837.

CASE OF CHRONIC LARYNGEAL DISEASE, COMPLICATED WITH PHTHISIS.

To the Editor of the Medical Gazette.

SIR,

THE accompanying case of chronic laryngeal disease, complicated with phthisis, and in which it was thought

necessary to perform tracheotomy, appears to me to offer many points of practical instruction. I therefore forward it, with some remarks, for insertion in the *MEDICAL GAZETTE*.

Your obedient servant,

GEORGE BURROWS, M.D.,
Assistant Physician to St. Bartholomew's
Hospital.

45, Queen Ann Street, Cavendish Square,
Sept. 30, 1837.

Thomas Lockwood, æt. 37, a carter, was admitted into St. Bartholomew's Hospital under my care, September 14th, 1837, in the following condition:—Pale, and somewhat emaciated; countenance rather anxious; skin warm and dry; voice gone, so that he can only speak in a hoarse whisper. He complains of uneasiness in the throat, which he refers to the top of the thyroid cartilage, where he feels as if the passage were "blocked up" during inspiration: there is actual pain felt when the thyroid cartilage is compressed between the thumb and finger. Difficulty of swallowing, especially liquids, which excite cough. Nothing morbid can be seen in the fauces. He has a constant cough, and expectorates a muco-purulent fluid, which is rather viscid. Difficulty of breathing, requiring the head and shoulders to be elevated, much increased by any exertion; no pain in the chest at present. Pulse 108; very thirsty; tongue moist, and whitish in the centre; appetite good; bowels open twice in the last twenty-four hours; evacuations loose.

Auscultation.—Air appears to pass freely through the lungs before and behind; no unnatural sounds are detected, but the loud tracheal sounds greatly interfere with the respiratory murmur in the lungs.

History.—He stated that he had been much exposed to the weather, and had been intemperate. Two years ago, in the winter, he had had pain in the chest, with cough. Last winter he again had pain in the chest, with cough. He has been unable to follow his employment for six weeks. A month ago his throat began to inconvenience him as at present, and has remained, during that period, much in its present condition. It appears that he has already had leeches and a blister applied to the throat.

The case was regarded as one of chronic laryngitis, consequent upon attacks of active inflammation of the mucous membrane of the trachea and bronchi. He was ordered eight leeches to the larynx; calomel, grs. ij., with opium, gr. $\frac{1}{4}$, night and morning, and acetate of morphia, gr. $\frac{1}{8}$ th, three times in the day.

The objects attempted by this plan of treatment were to subdue any local congestion of the larynx, to bring the system gradually under the influence of mercury, and allay the irritability of the glottis by the sedative.

15th.—The throat was rather easier after the application of the leeches, and deglutition performed with rather less difficulty. Six more leeches to the larynx.

16th.—He was found, this morning, at 5 A.M. by the nurse, insensible, breathing with extreme difficulty, and the face livid. Upon elevating his head, and giving him some wine and water, he partially rallied; but at ten o'clock A.M. he was found by the clinical clerk still insensible, covered with a profuse perspiration: his countenance pale, lips livid, the pupils contracted, the breathing laboured, the pulse 140. At 2 o'clock P.M. the breathing had gradually returned to nearly the same condition as when he was admitted: his pulse, however, was 140, and feeble; the finger nails were livid, and the respiration was carried on with considerable effort, and he had expectorated a large quantity of muco-purulent fluid.

Regarding the case as one of confirmed chronic laryngitis, and anticipating the recurrence of similar attacks of obstructed respiration, one of which would most probably terminate his life, I requested the opinions of my colleagues on the propriety of performing tracheotomy. I considered this opera-

tion not only justifiable, but absolutely essential to the man's safety, and by thus putting the larynx at rest, a chance would be afforded of subduing the serious disorganization going forward. In consultation on the case, much difference of opinion existed upon the propriety of an operation; and as there was at the moment no actual threatening of death from asphyxia, it was agreed to postpone the tracheotomy until more urgent necessity should arise.

He was ordered to take the Calomel and Opium pills every six hours; to continue the Morphia; and 5j. of strong Mercurial ointment to be rubbed in at the axilla.

The house-surgeons were also requested to lose no time in performing tracheotomy, should the paroxysm of dyspnoea return in the ensuing night.

17th, 10 o'clock, A.M.—He has had a quiet night, with sleep since 3, A.M. There has been no return of the extreme difficulty of breathing. His countenance is expressive of anxiety; the forehead covered with cold perspiration; the finger nails livid; pulse 140, and feeble. He says the breathing is easier, but it is evidently performed with considerable effort; tongue moist, furred in the centre, red at the tip and edges; bowels not open. He is evidently drowsy from the effects of morphia.

Auscultation.—The respiratory murmur is less audible over the mammary region of the right side than elsewhere; there is a suspicion of large crepitation about the scapulae. Both sides are resonant to percussion in the upper part of the chest, in front.—Discontinue the morphia, and in other respects to pursue the same plan of treatment.

About 4 o'clock, P.M. he was seen by my colleague, Dr. Roupell. It appeared to him that the closure of the glottis was becoming more complete, the difficulty of breathing increasing, and the risk of the man's life imminent, so that, although Dr. Roupell was opposed to the propriety of the operation at the previous consultation, he now made up his mind that it must be performed without delay. Mr. Stanley was sent for, and upon his arrival, he immediately agreed to the necessity of tracheotomy. After some slight hesitation the patient consented, and conducted himself throughout the operation with absolute stoicism. No-

thing untoward occurred in the operation, excepting the escape of a small quantity of blood from a vein, which was secured by a ligature.

A portion of the third and fourth cartilaginous rings of the trachea were removed, but its lining was too irritable to bear the introduction of a tube. The relief afforded to the patient was obvious, and which he manifested also by signs with his hand. He was left for the night with a nurse sitting by his bed, to assist him to food, and to watch him carefully. All remedies were suspended. Upon giving him some warm milk after the operation, it was observed to flow in part from the opening in the trachea. I should add that, upon subsequent occasions, when I saw him take fluids, none escaped from the tracheal opening.

The escape of liquids from the wound might give rise to the suspicion that the œsophagus was punctured by the knife of the operator. The dexterous and cautious manner in which the operation was performed assured us that such was not the cause of the phenomenon: it has been observed in other cases of disease and injury to the larynx, and no doubt arose from imperfect action of the arytenoid muscles which should close the glottis during deglutition.

18th.—He passed a quiet night, with sleep. His appearance is much more favourable; the skin is warm, and has lost its livid tint; pulse 120, with more power; breathing easier; the air passes principally through the opening in the trachea, although a considerable quantity passes through the nostrils. Whenever he swallows, cough is excited, and purulent mucus expelled both from the tracheal opening, and from the mouth. Pressure on the alæ of the thyroid cartilage still causes pain; tongue rather dry, coated with whitish fur; no mercurial fetor; one natural stool.

Eight leeches were applied to the larynx. Calomel, gr. iij., with Op. gr. j, to be taken night and morning. His diet to consist of warm milk and broth.

19th.—He has passed a restless night, without sleep; this morning (11, A.M.), the pulse is very frequent, and almost imperceptible; the nails are blue; he is unable to swallow, and is rapidly sinking. He died shortly afterwards, without any further change in the symptoms.

Examination of the body six hours after death.—*Larynx*.—The mucous membrane covering the arytenoid cartilages very much thickened and œdematous; a small ragged excavated ulcer existed on the superior edge of the right arytenoid cartilage; other small deep ulcers in the ventricles of the larynx; the whole mucous membrane of the larynx œdematous.

The trachea presented several patches of ulceration of considerable extent; in two or three situations the mucous membrane was entirely destroyed, and on the œsophageal aspect of the trachea, nearly opposite the opening, there was a small abscess in the submucous cellular tissue. An ulcer was situated close to the artificial opening in the trachea, and another a little below had completely laid bare the cartilages of the trachea. The lining of the trachea and bronchi intensely red. No ulceration or perforation of the œsophagus.

On opening the chest the lungs did not collapse; the two surfaces of pleura over the upper parts of the left lung were adherent by loose cellular tissue; the pleuræ at the upper part of the right lung were firmly adherent by condensed cellular tissue; in the lower part of the right pleura there was considerable effusion of straw-coloured serum, with shreds of lymph; the pleuræ in this part was enormously thickened by adventitious layers of coagulated lymph. In the apex of the right lung was a vomica which would have contained a good-sized orange. Throughout the right lung were numerous crude tubercles, advancing to the stage of softening; the substance of the lower lobes was considerably condensed. The left lung contained numerous granular tubercles in their nascent stage, but was otherwise healthy.

The heart healthy; the right cavities and coronary vessels distended with dark blood. The liver granulated; the kidneys healthy.

REMARKS.—The perusal of the foregoing case will naturally give rise to numerous reflections. Some will immediately say, how could such an error in the diagnosis of such extensive disease of the lungs be made by any one accustomed to employ auscultation? Others may think that the operation of tracheotomy ought not to have been performed excepting to rescue the pa-

tient from impending suffocation. To those who are accustomed to employ auscultation only occasionally, and are acquainted merely with the signs of disease made known to us through the sense of hearing in simple lesions of the lungs, it may appear culpable ignorance in the auscultator, that the cavity and pleuritic effusion in the right side of the chest were not detected. It would take greater space than is here allowable to defend the physician from such a severe condemnation. "The most experienced in the use of the stethoscope," writes the late Mr. John Wood, in his excellent paper on Inflammation of the Larynx and Bronchotomy (Medical and Chirurgical Transactions, vol. xvii.), "have regretted the little advantage derivable from its application in these cases, in consequence of the diminished supply of air to the lungs, and the noise and confusion produced by each violent effort of inspiration." In the Dublin Hospital Reports (vol. v. p. 80), Dr. Graves and Dr. Stokes have remarked, that "the difficulties which disease of the glottis causes, in deciding upon the exact state of the lungs, have not been sufficiently dwelt upon by authors. In point of fact, whenever the disease in the larynx is sufficient to cause sibilous breathing, all the stethoscopic phenomena depending on the characters of the respiration are singularly modified. . . . A knowledge of this fact is of great practical importance in investigating the state of the lungs in persons labouring under chronic laryngitis; an inquiry which ought never to be omitted, on account of the frequent occurrence of tubercles in persons afflicted with this disease. Thus we have seen *several cases of phthisis*, in which extensive excavations and numerous tubercles were found in the lungs on dissection, and yet during life no unequivocal evidence of this state of the lungs had been derived from the use of the stethoscope. The extreme weakness and altered tone of the voice in this disease (chronic laryngitis), deprives us of the assistance which the discovery of bronchophony, or pectoriloquism, would give in forming our diagnosis; and the protracted and gradual inspiration either prevents or renders very indistinct the valuable phenomena of crepitation, gargouillement, cavernous, bronchial, and puerile respiration. Under these circumstances, the general symptoms and percussion

are our only guides, and we have already seen how uncertain both these are."

Such opinions, emanating from these able physicians, are fully supported by the details of the foregoing case, wherein persons accustomed to an extensive employment of the stethoscope, from its first introduction into this country, were unable to detect the structural changes which had taken place in this man's lungs. But those who imagine that the stethoscope will never lead the careful observer into error, are recommended to peruse the admirable lectures of Dr. Latham, "On Subjects connected with Clinical Medicine." In Lecture 14, he treats "of the possible fallacies of auscultation—how it may lead to an erroneous diagnosis in pneumonia—in dilatation of the bronchi—in emphysema of the lungs;" and I might add (as has already been observed by Drs. Graves and Stokes), "in laryngeal obstructions."

But why were not the cavity and the pleuritic effusion discovered in the foregoing case? It is well known that pectoriloquy, gargouillement, and cavernous breathing, are the pathognomic signs of a cavity in the lungs. Our patient in this case was nearly in a state of aphonia; he could only "speak in a hoarse whisper." It was therefore hardly possible that pectoriloquy should be heard when the vocal sounds were so faint. The effect of coughing produced so much pain and distress in this case, that we not only refrained from asking the man to cough, while the ear was in apposition to the chest, but we were actually compelled to remove the ear from the chest as soon as the coughing commenced. This, probably, is the reason why no gurgling sounds were heard beneath the right clavicle, the seat of an extensive vomica. Perhaps cavernous breathing ought to have been detected in this same situation; but let it be borne in mind, that in these cases the loud tracheal sounds pass along the bronchi to every part of the lungs, and so embarrass the auscultator, that it is very difficult to distinguish cavernous, bronchial, and tracheal sounds, from each other.

Perhaps it may be said that the history and constitutional symptoms should have informed the careful physician that this was a case of phthisical laryngeal disease. The history, such as

could be obtained from a man who spoke with difficulty and pain, was not that of phthisis. He acknowledged no previous attacks of hæmoptysis nor diarrhoea, and, moreover, gave us accounts of distinct attacks of acute inflammation during the two preceding winters; besides, what hospital physician is not aware how little he can gain from the histories of urgent cases, as detailed by hospital patients? The constitutional symptoms arising from chronic bronchitis and phthisis are so similar, that it is almost impossible to make a diagnosis between the two without the aid of the stethoscope. But why was not the pleuritic effusion discovered by auscultation and percussion? In the hospital case-book it stands recorded, after as careful an auscultation, by Dr. Roupell and myself, as the man's strength would permit, "the respiratory murmur is less audible over the mammary region of the right side than elsewhere." Thus far the auscultation was correct, for that was the situation of the effusion; but our inferences were wrong. We immediately concluded that the right lung was not so good as the left; but all our suspicions being directed to the existence of tubercular cavities in the upper lobes, their usual situation, and the man never having spoken of pain in the right side, the pleuritic effusion was not detected.

Such appear to have been the various causes which completely masked those signs which would have enabled us to have formed a more correct diagnosis of the extent of disease in the lungs, beyond the laryngeal disease, which was ascertained on the admission of the patient.

The grounds on which the propriety of the operation was supported, have already been adverted to in the recital of the case; they are similar to those advocated by the late Mr. Wood. (Medical and Chirurgical Transactions, vol. xvii.) That much-lamented and talented young surgeon, after pointing out the importance of minute diagnostic research in these cases, and how the co-existence of pulmonary lesions will interfere with the prospect of a favourable issue, remarks, "We are not, however, to be deterred from operating, either from the supposition or assurance that the lungs are simultaneously disordered with the larynx. If the cure of the disease were therefore

out of the question (of which we cannot be positive), the operation, by lessening the frequent necessity of coughing to get rid of the increased mucous secretion, and the consequent fatigue to the lungs, at a time when their condition requires all possible repose, might yet obtain for the patient alleviation of distress and prolongation of life.

"The advantages of performing bronchotomy *very early* in cynanche laryngea, and the dangers attending its delay, have been exposed by Mr. Lawrence (Med. and Chir. Trans. vol. vi.) The Germans, however, claim the merit of having advised and practised the operation in cases of chronic inflammation of the larynx, where no *immediate assistance* was required to preserve life."

Upon these principles Mr. Wood advocated a much earlier resort to the operation than is usually adopted. He says, "when the symptoms of laryngitis are developed, and the inefficacy of ordinary means is evident from the daily increasing distress and weakness of the patient, from the failing voice, difficult respiration, and exhausting cough, tracheotomy should be at once performed; for if delayed to a later period, the chance of recovery will be materially lessened, and often entirely lost. The surgeon, too, often waits for symptoms which threaten immediate suffocation. Yielding to the fears and objections of the sick person and his friends, or similar considerations, he defers the use of the knife until extreme distress induces the dying man to submit to any mode of obtaining relief; and thus a measure most salutary, when adopted at the proper period, is brought into disrepute, because its employment is postponed till a favourable result is no longer possible."

Considerations analogous to the foregoing induced me to recommend the operation immediately after the first attack of obstructed respiration, in the case above recited.

Much additional relevant quotation might be adduced from a learned and elaborate paper by Mr. Lawrence, in vol. vi. of the Medical and Chirurgical Transactions; and to this paper is appended an interesting case, with observations, by Dr. Latham, who remarks, that "to vindicate the propriety of this operation, it is enough to know the situation of the disease; neither the his-

tory nor symptoms will fix its precise nature. The distinction of the cause will be lost in the magnitude of the irritation; so that whether there be inflammation of the membrane, ulceration of the cartilages of the larynx, or abscess in the cellular substance, or accidental lodgment of an extraneous body, the symptoms will probably be the same."

Thus much, then, for the difficulties and obscurity which attends laryngeal disease. It is hoped that, if the foregoing case does not reflect credit on the physician who treated it, that it may prove useful to his pupils and professional brethren.

ACUPUNCTURE IN HYDROCELE AND IN ASCITES.

To the Editor of the Medical Gazette.

SIR,

HAVING in a former letter hinted that the puncturation for the radical cure of hydrocele differed in some respects from that employed in the palliative treatment, although I have seen radical cures take place from the simple operation of a single puncture, yet, as acupuncture is not a radical cure in *all cases*, I beg to submit to my professional brethren the result of my own experience.

My method is to make a single puncture twice a week, for the first few weeks, so as to keep the tunica vaginalis in a collapsed state, and to bring on a healthy instead of a morbid secretion: by so doing, I find that the disposition to secrete water diminishes, and, therefore, if on examination I find only a drachm of fluid, I puncture. By pursuing this method, and employing at the same time the under-mentioned ointment* twice a-day, a radical cure is effected very speedily in recent hydrocele; but when the hydrocele has been of ancient date, the tunica vaginalis is so thickened that, although the fluid is absorbed, the parts do not appear to diminish, the thickening of the part preventing any evident contraction. Our object ought to be to simplify as much as possible the operations of surgery, and if we are desirous of emptying

the fluid at once, it can be done by a grooved needle without a canula; thus avoiding all unnecessary employment of instruments.

M. Velpeau, it seems, according to the accounts in the medical journals, tried puncturation in three cases of hydrocele without effect. Now if the puncture is made properly (and this can only be ascertained by a drop of water following the withdrawing of the needle), the absorption of the fluid will inevitably take place; although, where there is great thickening of parts, the volume of the scrotum is not so visibly lessened as in other hydroceles.

A valuable life ought not to be endangered by doubtful or hazardous experiments, although they may in some cases effect a speedy cure. Injections are strongly recommended, but they have frequently been productive of very serious, indeed fatal, results: it matters not what substance is employed, whether simply cold water, or wine and water, or the alcoholic solution of iodine so much lauded by M. Velpeau; the beneficial effects of which may, perhaps, depend more upon the alcohol itself than upon the iodine with which it is combined.

In a former letter I stated that Dr. Davis saw three cases of empyema get well after puncturation. I have now the additional satisfaction of recording the experience of Mr. King, who has had the courage to step out of the beaten track of routine practice, and, from analogical reasoning, to employ a new and, as it seems, a successful mode of treatment in *ascites*. Mr. King writes as follows:—

"6, Maddox-street, Sept. 25.

Dear Sir,—Having, in conjunction with a confrère in the profession (Mr. L'Estrange), applied acupuncture with some advantage to the treatment of ascites, I deem it right to make you acquainted with the circumstances of the case.

The subject of the operation is a tall man, of a constitution originally strong, but now a good deal worn, and I think between 50 and 60 years of age. The disease showed itself in July, and the patient remained a fortnight without medical aid. The man sent for Mr. L'Estrange, who, by the skilful administration of diuretics, obtained some

* R Hydriodatis Potassæ, ʒss.; Ung. Cetacci, ʒiss. M. f. unguentum.

amelioration. We first met in consultation on the 16th of August, and, after a few days, added mercury to the other means employed. As this was without benefit, and the respiration seemed much impeded at night, we thought of tapping; but the patient's strength was at so low an ebb that we did not feel certain that he could bear it. Upon deliberation, we were of opinion that some benefit might accrue to him from puncturing the abdomen with a long needle (of the size used for darning), so as to give the effused serum an opportunity of oozing from the peritoneal sac into the subcutaneous cellular tissue. The first puncture was made September 2d, on the right side, midway between the umbilicus and spine of the ilium, and was followed, as I withdrew the needle, by the issuing of three or four drops, one by one, of yellow serum. September 3d, another was made, anteriorly to the first. September 4th, there was a marked diminution in the tension. The abdomen was quite altered to the touch; the cellular tissue, which, in this region is two inches thick, presenting an œdematous state, in lieu of the tense unyielding condition it was in prior to the operations. A third puncture was made between the other two. September 7th, I made two more punctures.

9th.—Amelioration still marked, and the patient's general health is improving.

As every operation was followed by some amendment, I made three punctures on the 11th, three on the 15th, three on the 18th, five on the 20th, six on the 21st, six on the 22d, and seven this day. The result may be stated to be a diminution of four inches in the circumference of the abdomen, and an amendment of the patient's general health, such that he is able to walk out.

My present opinion is favourable to the employment of puncturation as a palliative. In some cases of ascites and empyema, when there is no organic disease, might not a cure be obtained by it?

If you think it may be useful to make this case known to the profession, you are quite at liberty to publish this letter.

Yours very truly,

T. KING.

To D. Lewis, Esq.

As the hydriodate of potash is an excellent adjuvant to puncturation in the cure of hydrocele, perhaps it may be

found to be equally efficient in other dropsies. The field is open for further experiments.—I remain, sir,

Yours truly,

D. LEWIS.

28, Artillery Place, West.
Bunhill Row, Sept. 26, 1837.

REMARKS ON THE USE
OF
TARTAR EMETIC AND OPIUM IN
SPASMODIC AFFECTIONS.

To the Editor of the Medical Gazette.

SIR,

AMONGST the various affections which engage the attention of the general practitioner, few are of more frequent occurrence than those denominated spasmodic. The suddenness of these attacks, with the fearful appearance of the symptoms, generally throw the friends of the patient into a state of the utmost alarm; it is therefore during the paroxysms that medical aid is most frequently sought. These circumstances, taken in combination with the anxiety which every medical practitioner has to relieve the extreme suffering in his patient, render the knowledge of such remedies, or such mode of treatment, as will certainly and speedily arrest the affection, exceedingly desirable. Every practitioner will, without doubt, endeavour to allay the natural feelings of alarm that arise in the minds of those by whom the patient is surrounded, by assuring them that the disease is not, generally speaking, of a dangerous nature. But this is not sufficient: the affection may progress from hour to hour, from day to day, notwithstanding all his remedies: one paroxysm may succeed another, until the strength of the patient is worn out, and exhausted nature at length finds repose in sleep. Such, I believe, is the general routine of the disorder. The remedies usually set forth in systematic works have been found, in many cases, totally inadequate to the desired end; so far, at least, as the paroxysm or fit is concerned. It is to this latter stage of the affection only, that the following remarks are intended to apply: the after-treatment will, of course, depend on the causes which have given rise to it.

In hysteria, for example, which, according to Cullen and other nosologists,

is placed in the class Neuroses, and order Spasmi (for the paroxysm is, undoubtedly, of a spasmodic nature) we have tonic contractions of various parts of the muscular system, occurring as well in the involuntary as in the voluntary muscles. These are dependent, I conceive, on a highly excited state of the brain and nervous system; and the tonic contractions or spasms continue more or less during the paroxysm. It may be argued that this state of the brain and nervous system is not primary, but only symptomatic of some local affection of a distant organ, and that we should therefore direct our attention to the "origo mali," if we hope to be successful in our treatment. But how frequently does it happen, in the treatment of a case, that we are obliged to give up for a time the remedies which are calculated to strike at the root of a disease, in order to combat some particular symptom which may have assumed a threatening aspect, and thus, as it were, for a time lose sight of those principles which form the basis of our treatment. In like manner, in a case of hysteria, I contend that we must leave the particular cause to after-treatment, while we direct our attention to the more formidable symptoms which manifest themselves during the paroxysm.

Now the whole class of antispasmodics, as they are termed, (and these are the remedies chiefly resorted to,) are, with scarcely a single exception, stimulants, and stimulants of a powerful nature. Such medicines, in this state of the system, I should say are not only inapplicable, but prejudicial. For what is the effect of a stimulant applied to a nervous trunk, but to increase its energy, and, consequently, the contractile power of the muscle it supplies? Or, if applied to the nervous extremities, as the surface of the stomach, an increase of action is the consequence. A stimulant, in fact, I need scarcely say, is "that which rouses the action or energy of a part," and, as before observed, all the medicines set down as antispasmodics are stimulants. What result, therefore, are we to anticipate from their employment in hysteria, spasm of the stomach, of the diaphragm, &c. but that they should increase the affection they were intended to subdue? By reasoning from cases somewhat analogous we shall arrive at similar conclusions. Who, for instance, would think of giving ammonia or assaetida to relieve a spasmodic stric-

ture? Who would prescribe a dose of æther or musk to allay the tonic contraction of the muscles about a dislocated joint, in order to facilitate its reduction? In a case of strangulated hernia, would any benefit be expected to accrue from the administration of camphor, valerian, castor, &c.? Such medicines would undoubtedly increase the spasm.

These views have been confirmed by incidental results in my own practice; and I appeal to the experience of other practitioners, whether their most strenuous endeavours to subdue an attack by the medicines above specified have not frequently proved abortive, even when assisted by the powerful aid of the lancet? Such must have been the result, I have no hesitation in saying, in very many instances. I could cite several cases of this description which I have attended, both alone and in conjunction with other practitioners, in which the disease has been prolonged during two and even three days under such a mode of treatment. I say prolonged, for I have now reason to be convinced, that by the employment of other means the symptoms might have been allayed in as many hours.

By what I have previously stated we are led to the conclusion, either that the affection is of a most obstinate nature, or that the general practice is founded on fallacious principles. The latter, I believe, is the case. It is necessary, therefore, that we should look for some other remedial agent possessing the power of relieving the excited state of the brain and nervous system, and thus allaying the tonic muscular contractions which characterize this class of diseases.

The remedy which I propose, and it is one which I have used with the greatest success for the last three years, is the tartar emetic, in combination with opium in some of its forms. The sedative effects of the opium are powerfully increased by uniting with it the antimonial salt, while its narcotic properties are diminished. The manner in which I prescribe it is the following:—Three or four grains of tartar emetic, with two drams of laudanum or one of Battley's sedative liquor of opium, and two ounces of water. A tea-spoonful of this mixture to be given every fifteen minutes, until relief is obtained, and afterwards every hour, until all symptoms of the affection have disappeared. Its first effect is generally to produce nausea, or even vomiting. The latter I encourage,

where, as is frequently the case, I have every reason to suspect that the spasm proceeds from improper or undigested food in the stomach, acting as a source of irritation. After this, the medicine is generally retained; *tolerance*, as Rasori describes it, being established, and the spasms speedily subside. It may be given in spasm of the stomach, diaphragm, spasmodic asthma, and during the paroxysm of hysteria, with the most beneficial results. I have administered it in such cases in the advanced stage of pregnancy; nor do I consider an irritable state of the stomach, with vomiting, any objection to the use of it, the sickness generally subsiding after the second or third dose. Should the symptoms be very urgent, if the case will in other respects allow of it, I do not hesitate to bleed, as a most powerful auxiliary; but phlebotomy may in general be dispensed with. Enemata are also at times beneficial, particularly where the attack is accompanied by constipation, though the tartar emetic sometimes produces evacuations from the bowels, and renders their administration unnecessary.

I am of opinion that this salt possesses a peculiar controlling or sedative power over the brain and nervous system. The beneficial result of Dr. Graves's treatment of the latter stage of typhus, where there was great cerebral excitement, with tartar emetic and opium, as recently published, bear me out in my conclusions. Rasori describes the operation of tartar emetic in large doses as *counter-stimulant*. And Dr. W. Philip speaks in terms of high commendation of the soothing effect of a combination of this salt with henbane, in cases of extreme nervous irritation; and even in maniacal cases, he says, "composure may generally be obtained."

While on this subject, I may also state that I can bear testimony to the good effects of the combination to which I have named, in the treatment of the more sthenic forms of delirium tremens, as recommended by M. Lepelletier, in his recent work on Tartar Emetic. He, however, appears to have given it alone, after large doses of opium had failed in procuring sleep. This is another strong proof of its sedative power.

In illustration of the above views, I could record a number of cases of which I have notes; but since the treatment is so very simple, I shall merely recom-

mend a trial of it to your numerous readers, being myself fully convinced of its efficacy.

There are, however, some other affections in which I have reason to believe that beneficial results might be obtained by a vigorous administration of these remedies; but as I have not yet had opportunities of putting them to the test, I shall merely make a few observations on the subject, which future investigation and experience may either confirm or set aside.

The diseases to which I refer are tetanus and hydrophobia. The former is undoubtedly a spasmodic affection, and very much allied in its pathological characters to those before mentioned. Dr. O'Beirne, in speaking of tetanus, says*, "he believes it to be seated in the anterior spinal cord, and probably in some parts of the brain. The change in these parts is only functional, and not connected with inflammation or organic lesion. All the symptoms are therefore the product of muscular action, dependent upon an accumulation or increased intensity of the *motific principle* residing in the anterior spinal column." In conformity with the above views, the remedial measure on which he places the most reliance is the use of tobacco enemata thrown into the colon. Now considering that these views are correct, I would suggest the employment of tartar emetic and opium in preference to the tobacco enemata: its action is on the same principle, and its use not attended with the same dangerous results which have frequently followed the employment of this powerful narcotic. The desperate character of the disease is no argument that we should resort to desperate remedies, provided safer ones will answer the purpose.

The latter affection (hydrophobia) is one upon which we are yet in great darkness. The number of well-authenticated cases we have on record, in which this affection could not be placed to the bite of a rabid animal, together with other peculiarities connected with it, lead me to the conclusion, that there are two varieties, as in tetanus, viz. the idiopathic and traumatic. The progress, too, of the disease in those who have been bitten by a rabid animal, is so opposed to all known laws of the effects of a morbid poison introduced

* Transactions of the British Association, Bristol 1836.

into the system, that I cannot but doubt their connexion. Mr. Travers says*, "that a morbid poison received into the circulation will sooner or later shew itself in an external form; but independently of that, it will give notice of its existence by a visible decline in the functions of health." This is not the case in hydrophobia; we have here, as in tetanus, no appreciable organic lesion, no external marks making their appearance during the progress of the affection. Ought we not, then, to dismiss the idea of such a poison lying dormant in the system for months, and even years, and then producing such a formidable train of symptoms? And ought we not to direct our treatment more to subdue the peculiar spasmodic symptoms which characterize the paroxysm? The tonquin remedy, which was formerly held in high repute as a specific in this disease, was composed of antimony, opium, and musk. This remedy, I imagine, would not have been so highly extolled, had it not been found beneficial in arresting at least, if not in curing, some cases of this dreadful affection. And when we consider that this was a secret remedy, the *modus operandi* of which was not understood, I think we may reasonably expect more satisfactory results from the judicious employment of tartar emetic and opium, which form the active ingredients in the old remedy. Your obedient servant,

R. YATES ACKERLEY, M.R.C.S.

ARTIFICIAL RESPIRATION,

DURING CONVULSIVE FITS IN CHILDREN.

To the Editor of the Medical Gazette.

SIR,

IN the number of the Edinburgh Medical and Surgical Journal for April 1818, is a paper by my respected friend Mr. Terry, now surgeon to the Northampton General Infirmary, detailing the successful employment of artificial respiration in the asphyxia of still-born children, and pointing out very forcibly the necessity of long continued perseverance even in apparently hopeless cases. In one instance related by him,

resuscitation took place after two hours and a half; and in the other, after one hour and three-quarters: in the latter instance the child being completely restored. I have met with several instances where I have been equally successful, when the action of the heart was not in the least perceptible, and where, for a very considerable time, all appearance of vitality was absent, and yet, after artificial respiration had been kept up for a time in which perseverance seemed hopeless, the action of the heart began to be distinguished, the livid aspect gave place to the colours of health, and the lungs at length were called into action.

My object now, however, is to call the attention of the profession to the application of the same means of artificial respiration in the asphyxia that is frequently met with during a convulsive fit in young infants. I believe that many a child has been lost—often and often the long-suspended act of respiration has ceased entirely—from the attendants limiting their measures to hot baths, frictions, cold water splashing to the face, stimulating applications to the nostrils, &c. &c., when the artificial inflation of the lungs, with the alternate expulsion of the air by pressing the chest and abdomen, would have restored the lost function, and recovered the child. I have met with several successful cases of this character, but the following is so striking that I forward it for publication in your valuable journal.

On the 20th March, 1837, an infant in Nottingham Place, five days old, had been in perfect health up to the moment that he was suddenly seized with a most severe attack of convulsions, the cause of which appeared to be the overloading the stomach the preceding evening. The fits began by the muscles of the eyes and face being thrown into violent clonic contractions, producing the most frightful contortions of the features; the pupils were dilated, the whole face and head turgid, as if the veins were going to burst, and and of a deep blue, or rather purple, colour. The respiratory muscles next took on the convulsive action, and caused the greatest oppression in the breathing; indeed the respiration was *completely stopped in most of the fits*, and recovered, after a frightful interval, by convulsive gasps and sobs, followed by deep sighs. The other muscles of

* On Constitutional Irritation.

the body and limbs then followed, and the whole muscular system became involved in the spasm. The following is an account of the fits and their duration:—

Interval.	Time of Attack.	Duration.
Three-quarters of an hour ..	Half-past 8, A.M.	First seizure, quarter of an hour.
Three-quarters of an hour ..	Half-past 9	Second, half an hour.
Half an hour	Quarter to 11 ..	Third, three-quarters of an hour.
Half an hour	Noon	Fourth and fifth, two short convulsions, quickly succeeding each other.
Quarter of an hour	1, P.M.	Sixth, quarter of an hour.
Three quarters of an hour ..	Quarter to 2....	Seventh, ten minutes.
Thirty-three minutes	20 minutes to 3.	Eighth, twelve minutes.
One hour, 25 minutes.....	25 min. past 3..	Ninth, eight minutes.
Half an hour	5 minutes to 5.	Tenth, twenty eight minutes.
Twenty minutes	6	Eleventh, half an hour.
One hour and a quarter	10 minutes to 7.	Twelfth, three-quarters of an hour.
	10 minutes to 9.	Thirteenth, twenty-three minutes.

The main indication in the treatment was to get the bowels to act, and to relieve the pressure on the brain. The child had been put into a hot bath by the nurse, which was repeated during the second attack, without apparent benefit. A leech was applied on the frontal bone, near the fontanelle; half a grain of calomel and a grain and a half of jalap, with a tea-spoonful of castor-oil, were given every four hours, and the lower part of the bowels repeatedly evacuated by injections of soap and water and castor-oil. The strength was kept up by injections of jelly, with a few drops of sal volatile or brandy in them. After the twelfth fit, the bowels acted for the first time from the higher intestines copiously; after which there was only one mild though long seizure, when they entirely ceased; the child went to sleep, and was perfectly well the next day, and has remained so ever since, without the slightest symptom of any return.

The whole case shows to what extent functional mischief may affect the brain and spinal column, excited by sympathetic irritation, without any inflammation or change of structure, for the fits ceased almost immediately after the operation of the medicine administered by the mouth; as, though the enema emptied the large intestines, this did not have any effect upon the symptoms, the obstruction seeming to be in the upper portion of the canal.

The pressure produced upon the brain

was such that respiration was entirely suspended during the greater part of the fits, and even the action of the heart could not be felt for more than ten minutes in the third and twelfth fits, and the child lay to all appearance dead. It was at such times that I proceeded to restore the suspended functions by artificially inflating the lungs, in the manner described by Mr. Terry—namely, by breathing into the mouth of the infant from my own, closing the nostrils, and compressing the thorax after each inflation; observing the natural periods of frequency as much as possible. I am quite convinced the child would have been lost, had it not been for the artificial aid thus afforded to nature in the severe struggle, till the offending matter was expelled. By means of the artificial respiration, the colour (especially of the face and lips) turned from purple to red, but still there was no breathing, till a convulsive gasp announced the termination of the fit.

I am aware that some have recommended a tube to be passed into the larynx, in preference to breathing into the mouth; and also many have objected to the employment of one's own breath, as the expired air is loaded with carbonic acid, and deprived of a portion (though a small one) of its oxygen. The success of the plan I employed, however, is quite sufficient to justify its use, and it is much more easily effected than by means of the tube, which has

sometimes seriously injured the soft parts, and is too readily displaced. A purer air would no doubt be more proper, but unless its temperature could also be kept up to that of the human body, we should lose one of its restorative properties, or perhaps as much consequence as the other. In the cases where artificial respiration was kept up in animals under the influence of narcotic poisons, by Sir B. Brodie, as detailed in his Croonian Lectures, the temperature of the air employed was thus artificially elevated; but in the hurry and confusion of a still-born child or a convulsive fit, there is no time to make the necessary preparations. What I would most wish to insist upon, is the necessity of perseverance in such instances; and perhaps the history of the case I have given may induce others to persevere in the same manner to the very last (*lateat scintilla forsitan*), and thus perhaps, as in this instance, restore an only child to its anxious parents.

Your obedient servant,
LAWSON CAPE, M.D.

EFFECTS OF A BLOW ON THE STOMACH.

REMARKS ON DR. HOLLAND'S PAPER.

To the Editor of the Medical Gazette.

SIR,

IF you should deem the following remarks worthy of insertion in your widely disseminated and duly appreciated journal, by so doing you will oblige,

Your obedient servant,
H. G. HARBORD.

South Dispensary, Liverpool,
Sept. 25, 1837.

The eyes of the scientific world, or at least of the British portion of it, have been, and still are, directed to the proceedings at the meetings of the British Association recently held at Liverpool. It is, therefore, but just that the medical part of the community should turn their attention to some of the disputed points mooted at the meetings of the medical section. I was much struck,

among others, with a paper by Dr. Holland (of Sheffield), entitled, "An investigation into the cause of death from a blow on the stomach, with remarks on the means best calculated to restore animation."

After mentioning the commonly received notions, such as a nervous shock from injury to the semilunar ganglion producing paralysis of the heart, and adducing evidence that the heart did not cease to contract immediately on the receipt of such injury, and noticing the opinions of some with regard to the eighth pair of nerves, he proceeded to state his own views, which were nearly as follows:—

Death from such a blow generally occurred in pugilistic encounters, when the circulating system was much excited, and such a blow was generally directed from below upwards. Now the effect of this would be, in his opinion, to compress the aorta, among other important parts, between the fist and bodies of the vertebrae, which curve forward at this point. The consequence would be, that the current of arterial blood would be, at the time, stopped; and not only so, but, from the direction of the blow, driven backwards upon the heart, and so cause a retrograde movement, which would drive a mass of blood into the left ventricle, and by thus overpowering it, produce death. He stated he was convinced this could take place, for he had succeeded in distending the left ventricle by *gently* injecting a fluid through the aorta. The Doctor also mentioned, that a blow at the angle of the jaw, it was well known by pugilists, would produce insensibility; but this he referred to a different cause, viz. the sudden impulsion of the blood through the carotids upon the brain.

In fine, three points were assumed, and considered by the learned Doctor to be proved, viz. that—1st, the aorta was so situated as likely to be influenced in the manner stated; 2dly, that a blow given with great violence would cause a retrograde motion of blood, and its entrance into the left ventricle; and 3dly, that the latter would cause death.

Dr. Williams noticed the remark about the semilunar valves allowing the injected fluid to pass them, when *gently* thrown into the aorta, but clearly

proved that blood, or any fluid, could be driven into the ventricle *only* by being *gently* propelled, and thus allowing it to trickle into the heart, without insinuating itself between the valves and aorta: this fact is so well known to all anatomical preparation makers, that it requires no comment. Sir James Murray objected to Dr. Holland's views, that although the blood might be driven back by the blow, it would be generally diffused throughout the enlarged portion of the aorta, innominata, subclavians, and other arteries arising from it; or, even supposing it should rupture or pass the valves, he did not see how such a small quantity in excess could so materially affect the heart's action. Dr. James Johnson thought that the effects might be referrible, in some measure, to paralysis of the diaphragm from the blow. Dr. Copland suggested, that the heart itself might be injured through the diaphragm.

Had I been one who had already earned fame by research and patient investigation, I would have risen in the "great assembly," and there made known my opinions; but I was awed into silence by the presence of such a galaxy of genius.

It is the lot of few, and master minds only, to strike out new and original lines of thought—to embellish the annals of science with new and important discoveries—to establish systems vast and comprehensive. On these men we look with an eye of respect and reverence; and as we follow them "*haud passibus aequis*," along the paths they have opened before us, we stay a while to gather what they may have passed in their haste, or neglected in their approach to the grand object of their pursuits; and we think ourselves fortunate if, in this way, we obtain any fact, however unimportant—any truth, however simple; and we rejoice thus to add our mite to the common cause of science. It is with such feelings as these that I have entered upon the investigation of this subject; and I shall now venture to lay before your readers my deductions from the evidence and opinions before us, and my views of the matter.

Let us trace the probable effects of a blow directed backwards and upwards in the epigastric region, during an excited state of the circulation. In the

first place, the aorta would be compressed against the spine, and thus the current of blood momentarily stopped; and not only so, but driven backwards towards the heart. Again, independently of the effects of the concussion on the vena cava or semilunar ganglion, the diaphragm would be driven upwards, diminishing the capacity of the chest, the calibre of which would be still further diminished by the ribs being forcibly drawn downwards and inwards. Besides this, the blow (as suggested by Dr. Copland) might have some immediate effect upon the heart itself, especially if at all directed to the left side. Having now, in imagination pictured the primary effects, let us follow them still further.

The retrograde or impeded current of blood meeting with that portion just ejected from the heart, must expend itself somewhere. Five large passages present themselves; the largest, however, viz. that which leads to the left ventricle, is immediately closed by means of the semilunar valves, and the carotids being at the summit of the arch of the aorta, the force of the two portions of blood, namely, that from the heart, and that driven backwards upon it, would be principally expended upon them, although the subclavians would, undoubtedly, have more than their share, though not to such an excess as the carotids. The natural consequence of this would be, either to congest the brain to an extent incompatible with the due performance of the vital functions, or to cause the rupture of a vessel within or upon it; the tendency to congestion being materially increased by the mechanical obstructions to respiration, from the diminished capacity of the chest preventing the free return of venous blood to the right side of the heart; and all these various causes acting and reacting one on the other, would tend to extinguish the vital spark, already enfeebled by the first shock.

Having now extended my remarks to a length almost unwarrantable, I must apologize for such transgression, and conclude by hoping that these views, if erroneous, may be deemed worthy of refutation, as the subject is an important one.

SOLID NITRATE OF SILVER IN
GONORRHŒA IN FEMALES.

—
To the Editor of the Medical Gazette.

SIR,

IN your number for the 9th ult. I find a letter from Dr. McCune Smith, in which he speaks with disapprobation of the application of solid nitrate of silver in gonorrhœa.

It is easy to start objections to any point, but not quite so easy to prove them to be such. Since Dr. Hannay made known to the public, through the medium of your valuable journal, the mode of applying the solid nitrate of silver in gonorrhœa, I have had opportunities of trying it, and seeing it tried, in between thirty and forty cases, the result of which enables me to state, that it is not only a most efficacious remedy, but that it is unattended with *any bad symptoms*, and excites scarcely any uneasiness. I beg you to understand that I am now speaking of simple gonorrhœa. When ulcerations accompany the vaginal discharge, there is some pain experienced on the introduction of the nitrate of silver, but it is not so severe as Dr. McCune Smith would have us believe.

As regards the success of this plan of treatment, I have invariably found that, in four-and-twenty hours after the application of the solid nitrate of silver, the nature of the discharge has undergone a considerable change; what was thick and purulent became thin and watery, and this, in the course of a few days, ceased altogether.

It is stated that the patients frequently experience relapses. I will not say that such may not be the case, especially in the hands of such feeling practitioners as Dr. McCune Smith, though it certainly never occurred in those to whom I applied it.

Query.—Has Dr. Smith ever used the solid nitrate of silver, or seen it used, in cases of gonorrhœa? He either has, or has not. If he has, though in a few instances, I suspect he must have written in direct opposition to the palpable evidence of his senses. And if he has not, it would have been wise in him to have acted a silent part. Be this as it may, I cannot help thinking that the following phrase peculiarly applies to those who draw practical conclusions

without practical premises—“*Damnant quod non intelligunt.*”

Your obedient servant,

HENRY SOMERSET TAYLOR.

Hereford,
26th Sept. 1837.

FŒTUS—SIGNS OF ITS VITALITY.

—
To the Editor of the Medical Gazette.

SIR,

I WAS some time since called by a very intelligent surgeon, residing at Maida Hill, to bring on premature labour in a patient of his, who was supposed to be carrying a dead child, and who had, on a previous occasion, suffered materially from not having been delivered artificially after the child had been putrid a considerable time. On applying the stethoscope over the gravid uterus, the “bruit placentaire” and sound of the fetal heart were wanting; but as the os uteri was not so low down as at the seventh month of utero-gestation, and as her general health was good, and Mr. Wing constantly at hand in case of emergency, I thought it better to allow some days to elapse before premature labour should be induced, and arranged that we should meet again in a few days. At the appointed time we accordingly did meet; and just as I was about to examine her she gave a slight start, and directed my attention to her abdomen, where I distinctly felt the angular projection of a limb of the fœtus, which gradually receded, as is pretty generally the case when the child is alive. Mr. Wing observed the same; and the patient remarked that this often occurred. We congratulated ourselves that we had not brought on the labour before the seventh month, as we had here one of the generally-received indications that the fœtus was alive. On making an examination per vaginam, the os uteri was found considerably shortened; and when she was in the erect posture, that peculiar sensation, called “ballotement” by the French obstetric authors, was absent. In ten days after our last visit labour came on naturally, and she was delivered of a child, which had evidently been dead some weeks. This case is peculiarly interesting, as shewing the certainty with which we may form our

diagnosis as to the existence *in utero* of a living child by means of the stethoscope, when, in all probability, without its assistance we should be in error.

Your very obedient servant,
GEORGE S. LILBURN, M.D.

24, Harley Street,
Sept. 27th, 1837.

CASE OF
AMPUTATION OF A PART OF THE
LOWER JAW.

By J. ADAIR LAWRIE, M.D.

Professor of Surgery, Andersonian University,
Glasgow; Senior Surgeon, Glasgow Royal Infirmary.

HELEN JOHNSTON, *æt.* 67, Saltmarket, was admitted into the Glasgow Royal Infirmary, June 9, 1834. The following description and reports are abridged from the hospital journals:—

The gum covering the front half of lower jaw presents a foul, irregular, jagged ulcer, discharging a fetid serum, and is the seat of stinging pain. Alveolar processes seem destroyed, and the teeth, as far back as the bicuspidati, on either side, are loose, and project from the ulcerated surface. The bone is felt bare in front, and laterally, on either side, thickened; on the right, nearly as far back as the angle. A tumor, having many of the characters described, and about the size of a hen's egg, is situated under forepart of tongue, and between it and posterior surface of jaw bone, and appears intimately connected with the ulcer on the gum. The tongue is raised and thrown back by this swelling, but, as far as can be ascertained, is not implicated in the disease. The chin is rendered prominent by the swelling of the gums, and, together with the under lip, is unnaturally livid; but there is no trace of disease on any part of the mucous membrane of the cheeks or lips. Articulation and deglutition impeded. She is much annoyed with the fetid discharge, and her condition is consequently very uncomfortable; pulse natural; general health rather impaired; countenance good. A tumor of considerable size was cut from the same situation as the present a year ago in this house. It reappeared five months since.

June 14th. — At a consultation, the

majority were of opinion that excision of the greater portion of the inferior maxilla was advisable, recommending, at the same time, the extraction of the loose teeth, and the delay of a few days thereafter to ascertain more accurately the state of the tongue.

Some teeth have accordingly been removed; and on further examination, the tongue seems sound.

25th. — The nature of the disease and the extent of the proposed operation having been explained to the patient, she requested to be allowed to leave the hospital to consult her friends. She returned two days ago, and having declared her willingness to submit to whatever might be deemed proper, the following operation was performed this afternoon:—

The patient being seated on a chair, her head turned back and supported on the chest of one of the surgeons, an incision was made from the left angle of the mouth, through the entire substance of the lip, nearly perpendicularly downwards as far as the inferior horizontal edge of the lower jaw; the bone thereby laid bare externally, but no incision or separation of the bone from the soft part made inside the mouth. The needle of Dr. Jeffray's chain-saw was passed round the bone (inside the mouth) and the saw drawn through. The saw was worked without a single check by the operator, standing on a stool behind the patient. A similar procedure was adopted on the right side, but from the more exterior thickening of the periosteum, the incision was carried further back, and the bone sawn close to the masseter muscle. The under lip and integuments were now dissected from the front of the tumor and bone; the knife was passed between the tumor and the tongue, and the whole of the diseased parts, together with the portion of bone sawn, removed. The time occupied was seven minutes. The bleeding vessels were tied; the flap formed by the under lip was replaced and retained by sticking plaster and bandage, and the patient walked, unassisted, to her ward. Pressure was so successfully applied by my assistants to the bleeding vessels, that not more than five ounces of blood were lost. So soon as the attachments of the muscles of the tongue to the bone were cut, the tongue was pulled back into the throat; and had not this been foreseen and steadily prevented, the

patient must have been suffocated. It was easily obviated by one of the assistants carrying his finger towards the root of the tongue, and pressing the organ downwards and forwards. To assist this, and afford the means of readily laying hold of the tongue, should the tendency return after the patient should be in bed, a ligature was passed through the tongue, near its point, and attached to the dressings. About an hour after the operation, hæmorrhage came on to such an extent as to compel the removal of the dressings and stitches. Two or three vessels were tied under the tongue. The instant the stitches were cut the tongue again receded, and was even more troublesome than during the operation. The dressings having been reapplied, the tongue retained its proper position, and the respiration continued ever afterwards perfectly easy.

July 7th.—Adhesion has succeeded on left side, but failed on right. The edges of the wound on the right side being quite clear, and there being no appearance of a return of the disease, the granulations and a slight paring of skin were removed by the scalpel, and the edges brought accurately into contact by pins and a stitch, without an external dressing. The adhesion was quite successful, and on the 12th of August she left the hospital in perfect health.

About two months after she left the hospital, the disease seemed to have returned, in the form of enlarged glands, on the left side of the neck, towards the angle of the jaw, and immediately above the left side of the sternum,—the latter of considerable size. Those towards the angle of the jaw proved to be the result of irritation, and not of extension of malignant disease, because at the end of a few weeks they suppurated, discharged their contents, and disappeared. That at the top of the sternum diminished considerably; and although it has not disappeared, it gives so little annoyance that the old woman is not even aware of its existence.

I saw widow Johnston a few days ago. She continues in good health: the mouth and neck are quite free from disease; the swelling above the sternum stationary, and free from pain. She expresses herself satisfied with the result of the operation. The disfigurement of her face is very slight,

and consists only of a shortening of the under jaw; the remains of the jaw on either side have approximated, and lie within half an inch of each other, apparently loosely connected by ligament. She articulates very distinctly, swallows liquids as well as she ever did, and can masticate bread and soft food. The prehensive power of the under lip is impaired, requiring her to push solid food farther into her mouth than before the operation. She cannot protrude her tongue beyond her under lip. She says she did not give a true account of her age at the time of the operation, lest I should be deterred from undertaking it; she was then upwards of 70, and must now be upwards of 73.

The surface of the tumor after the operation was granular, and of a greyish colour. Internally it was fibrous, firm, paler than externally, and not at any point softened. It was firmly adherent to the gums, which had very much the same external appearance as the tumor. A considerable portion of the upper surface of the bone amputated, was removed by ulcerative absorption. Towards the right side, the alveolar processes and cancelli of the bone were softened.

REMARKS.—The successful result of this operation is my reason for publishing it; for although apparently formidable, and the second of the kind performed in this large city, it is by no means difficult to execute. Its sole value (and the same may be said of all operations performed for the removal of supposed malignant disease), consists in its success. The grand aim of the surgeon in such cases, is to ascertain, from external characters and history, what tumors are likely to return after operation, and what not; a diagnosis so difficult to form, that our best and most experienced surgeons are often at fault. The internal structure of tumors—I say it with due deference to our pathologists—is of very minor importance; because, as that can only be ascertained after removal, a prognosis founded on it comes too late. It is of importance to connect the internal structure with the history and external characters; but, I repeat, the latter must ever be the subject for the diligent study of the practical surgeon. The details of the present case, extracted from the public journals of an hospital, are not so minute in this respect as I could wish;

the following, however, are worthy of remark. The *history*: arising without any known cause, slow in its progress, returning in the same spot after removal, and not implicating (except by slow immediate extensions) the parts in the neighbourhood—in close contact with delicate parts (the tongue, and mucous membrane of the cheeks and lips), and leaving them sound—the age of the patient (70), her general health, colour, and expression of countenance good. *External characters*: irregular and granular on its surface; colour light; not hard to the touch; the gums ulcerated, but not fungous; the discharges fetid, not hæmorrhagic; the pain stinging, not severe. Its situation, the cellular tissue under the fore-part of the tongue.

The history after the operation is interesting, inasmuch as what appeared to be a return of the disease ended in suppuration, and healed without difficulty.

I cannot help thinking that a careful record of the history of similar cases before operation, and a statement of the result, whether successful or unsuccessful, three years afterwards, together with minute details of their *external* characters, might, at no very distant period, lead to a more safe and scientific treatment than even our best surgeons at present pretend to.

It is unnecessary to say much regarding the mode of operating adopted in this case. It appeared to me to combine facility and rapidity of performance, with the very important advantage of giving a clear view of the diseased parts, and those among which they lay. It had the disadvantage of being rather difficult to heal.

Some distinguished surgeons, among whom I may mention Velpeau and Richerand, object strongly to the removal of the chin, on the grounds that the attachment of the genio-hyo-glossus muscle to the chin being destroyed, the patient incurs the risk of dying of suffocation during the operation, in consequence of the retrocession of the tongue, or ultimately of inanition, from inability to swallow. The first of these objections is so far well founded, as to require the sedulous attention of the operator. M. Lallemand, in a similar case, nearly lost his patient on the operating table, and only saved him by opening the larynx. He appears not to have been aware that the tongue would recede.

His assistants were pupils, and were so much alarmed by the frightful appearance of the patient, as to be of little service. He at first attempted to pull the tongue forward; but the bleeding was so profuse, that he was forced to let go the tongue, and leave his patient in a state of asphyxia, until he freely cauterized the bleeding surface. He then opened the crico-thyroid membrane, inserted a canula, and dressed the wound. A knowledge of this case prepared me for a similar difficulty in Johnston's, and I found that the moment the genio-hyo-glossus muscle was cut, the tongue receded, and the patient would have been suffocated. Had I not been properly assisted, I might, perhaps, have been compelled to follow Lallemand's example; but I was saved all uneasiness by Dr. Pagan putting his finger on the root of the tongue, and pressing it downwards and forwards.

One circumstance struck me as remarkable: as soon as the dressings were applied, and support given to the under and fore part of the tongue, its tendency to recede immediately ceased, and the poor woman breathed with ease. When the dressings were removed, on account of the secondary hæmorrhage, the tongue was instantly and spasmodically drawn into the pharynx, and was with more difficulty kept forward than during the operation. No sooner, however, were the dressings re-applied, than it regained and retained its natural position. This fact is at once physiologically curious and practically important.

The second objection, that the patient must die of inanition, is supported by a case in which the unfortunate occurrence took place in a patient under the care of Richerand, in the Hospital St. Louis, in 1822. Probably that case presented some unusual peculiarity. The tongue is reported to have been quite immovable. Johnston never experienced much difficulty in swallowing, and Lallemand's patient drank with facility immediately after the operation. A successful case, in many respects resembling Johnston's, is related by Genroul: he removed a portion of the lip and integuments, although sound; a procedure which Johnston's case proves to be quite unnecessary.

Glasgow, Sept. 1837.

TUBERCULAR LEPROSY.

To the Editor of the Medical Gazette.

SIR,

CONCEIVING that your numerous readers will be interested in the perusal of the following brief analysis of a most important, because practical, paper, by Dr. Hancock, lately read at the Medical Section of the British Association, at Liverpool, I transmit the same to you for insertion in your excellent GAZETTE. It relates to one of the most dreadful chronic disorders incident to humanity—viz. Tubercular Leprosy; the *Lepra Arabum*, or *Cocobae* of the Africans, which Dr. H. has succeeded in identifying with the *Ara-apatta* of the Caribs, and the *Radesyge* of the northern nations of Europe. This disease is unfortunately very prevalent in the West Indian colonies and British Guiana; but it would seem that the native Indians, amongst whom Dr. Hancock sojourned during many years, possess much useful and practical knowledge on this and other important subjects; at least they employ very effective remedies and modes of treatment in divers inveterate maladies, which, in the civilized countries of Europe, are justly regarded as the very opprobria of the healing art.—I am, sir,

Your obedient servant,

C. MACKENZIE.

London, Sept. 27, 1837.

The first part of Dr. H.'s paper went to show that the disease in question has been usually confounded with elephantiasis, or what is termed the Barbadoes *leg* and Siam disease; in which the skin and soft parts about the leg and ankle become so enlarged as to bear a close resemblance to the leg and foot of an elephant—a local disease confined to the affected limb, and perfectly distinct from the true *Lepra Arabum*, in which the whole body, or the entire mass of fluids and solids, appears to be implicated.

In treating of the causes and symptoms of the disease, Dr. Hancock thought that it obviously consisted in a vitiated condition of the blood and serous fluids; but this appeared to be connected, either as cause or effect, with obstructions of the absorbing and secreting vessels; this, together with a peculiar

predisposing diathesis, determines the form of the disease. The obstruction and a faulty secretion produce serous deposits under the skin, forming the tubercles, knobs, or indurations, which soon characterize the disease; in proportion as they increase in number and magnitude, the circulation, with the absorbing, secreting, and depurative processes, become daily more obstructed. The process being slow and gradual, the humour solidifies almost as fast as it transcends. The tubercles are of a copper or leaden colour, and more numerous on the legs and thighs. There is stiffness of the eyelids and thickening of the palpebra: the voice becomes hoarse and nasal, and the respiration more or less affected. Varicose veins and knotty pustules are observed about the root of the tongue; and in the advanced stage the whole countenance becomes distorted, full of knobs and tubercles, and of a hideous aspect. In the last or ulcerative stage, the hairs fall off from the eyelids, eyebrows, chin, and other parts; the toes are swelled, and crack with dry fissures, and the skin becomes quite callous and insensible. A corruption of the whole mass of humours, and general disorganization of the solids, ensue; hectic fever supervenes, and terminates the existence of the miserable sufferer. In some cases a few solitary symptoms will occur, whilst in others many will appear almost simultaneously.

Dr. Hancock adduced a variety of arguments to prove the perfect identity of *Lepra Arabum* with the *Radesyge* of Norway, Sweden, and other northern countries. He had been led to investigate this part of the subject from having seen, with surprise, in the 18th volume of the Edinburgh Medical and Surgical Journal, a summary of symptoms drawn up from Holst, Stowe, and other writers, with the view to prove their *non-identity*. The objections contained therein were shewn to arise from a misapprehension of the subject, or from an over anxiety to establish certain preconceived opinions. Not only did the whole train of symptoms agree in every particular, but also the general progress of the two diseases, and the morbid changes which take place. Dissections of those who had died of leprosy had not afforded to the writer evidence of such changes in the genital organs, as have been adverted to by certain

writers. It was worthy of remark, that the appearances noticed by different authors, in the Radesyge of northern Europe, are all occasionally observable in the Cocobae of the West Indian colonies, from which it is clear that varieties have been multiplied without reason, or for any practical purpose, but tending only to complicate and create confusion. Dr. H. had, in no instance, known the Cocobae (*Lepra Arabum*) to be communicated by the husband to the wife, nor *vice versa*; so that, notwithstanding the prevalent opinion to the contrary, he had long ago regarded it as void of contagion; yet he was almost induced to think that, under predisposition and other concurring causes, the disease may, in the *ulcerative stage*, be communicated. It seems that *white* persons in the colonies avoid touching a person infected with leprosy; and they generally segregate the lepers on a distant part of the respective plantations.

Having briefly stated the results of some post-mortem examinations in the disease, Dr. H. proceeded to detail the methods he had found most effective in its cure. When attended to early, the symptoms were easily arrested by the use of saline laxatives, with antimonials, anodynes, diaphoretics, vapour baths, and frictions; bleeding, spare diet, and the several means for promoting *lymphatic absorption*, and all thesecretions, especially by perspiration. The advantage of such means, duly persisted in, was evinced in the relief obtained for the patient, and rendered obvious to others by the foul and fœtid miasms evolved, as well as by the exuvia thus thrown off from the surface of the body. Cases which had occurred during Dr. H.'s practice in Guiana were adduced as illustrative of the advantages obtained over the disease by calling in the united aid of the various remedies.

As auxiliaries, opium and the *Coonuparu* (the leaves of a plant of the Euphorbiaceæ family), were found to afford essential aids, along with the alternate use of warm vapour baths and cold affusions,—means which the author has found to be equally beneficial in divers chronic diseases. Moderate bleeding was often found to augment the strength, and greatly to facilitate the cure; along with the moderate use of tonics, diaphoretics, and iodine. The sensation of lassitude and debility often depends on

hypertrophy or congestion. The morbid growths, or fungoid tubercles, in this disease, are nourished by excess of blood; they resemble those of cancer, and by many they have been considered equally incurable.

The Indians of Guiana resort to fomentations, baths, and to a drink of the bark of a tree called *Mouca*, with the root of a vine, *Paramaroora*—a species of *Cissus*—and the bark of *Waiacono* (guaiacum), the infusion of which is fermented with honey. They use also the bark of the tree "*Tamootu*," a nondescript. These simple methods of the American natives are likewise of vast efficiency in arresting the most pernicious fevers, dysentery, and a multitude of ailments both acute and chronic.

MEDICAL ATTENDANCE ON THE POOR.

To the Editor of the Medical Gazette.

SIR,

IF you think your readers are not quite tired of every thing appertaining to the poor-laws, more especially that part of them connected with medical attendance, perhaps you may find room for the following observations.

It appears very clearly that the medical profession is to look for no support from the government, or any of its officers; I think, therefore, they must look to their own interests, and by a combination of action produce that beneficial result which they can never obtain by individual exertion alone. I believe every one who is capable of judging—that is, every one who knows the extent of attendance, and the quantity of medicine required for the poor—considers that the medical attendant, as at present paid, is very badly remunerated. This, I believe, is allowed by all; but it is stated in answer, that the grievance cannot be remedied; that it arises out of the absolute necessity of lessening the poor-rates; that the attendance is not compulsory; and that if the resident practitioners do not like the terms offered, the Assistant-Commissioner will send a person to take the office. This is not only threatened, but it has been acted on in several instances; and the medical practitioner who, after a regular and necessarily expensive education, has by a great outlay of money,

and by assiduous and active exertion, established a connexion just sufficient to obtain the necessaries of life for his wife and family, has found his future prospects blighted by the introduction of a young man (perhaps who has just finished his education), under the influential interest of the Commissioner and his officers.

There appears to me but one remedy for this grievance, which is the following:—Let every gentleman who is eligible, and desirous of serving the office of medical attendant to a Union, send in his name to any one of his brethren who may be fixed on; and when the names are collected, let them be drawn from a box in the presence of the whole, and then let the gentleman whose name is first drawn be considered the person who is to have the appointment for a year.

Now, as to the terms of remuneration, I propose that in a wide agricultural district the practitioner be paid sixpence a head; in towns and manufacturing districts, fourpence.

I should be willing that a gentleman thus appointed should be under the directions of the Board of Guardians, for I know no other authority to which he could be responsible; and should the Board find him incompetent or unwilling to perform his legitimate duties, they might remove him, and let the names be drawn again to supply his place. Should the Commissioners absolutely refuse to appoint a gentleman thus presenting himself for their approval, and send a stranger to fill the office, I think the best method of counteracting this would be the following:—I should have it publicly known that every person who allowed himself, under these circumstances, to be appointed to a Union, should be sent to Coventry by his brethren, and have his name advertised in every medical periodical. I fear there are some few in our profession, as there are in all professions, who prefer their own personal advantage, however obtained, to upholding the character of that branch of science to which they unfortunately belong; but I trust they are not sufficiently numerous to interfere with the plan I have proposed.

Here I naturally expect to be asked this question—Will the Commissioners permit this? Most certainly not, if they can prevent it, for it will take away

their power of authority, which authority they have exercised in several instances in a most ungentlemanly and shameful manner. I am speaking from facts: they have treated many gentlemen of equal, if not superior education to themselves, as if they belonged to the lowest class of tradesmen, who were waiting on their high mightinesses with a tender for shoes or bread—refusing to hear any observations they may have wished to make—telling them, “totidem verbis,” they may either take the contract or leave it—that if no resident practitioner will take it, they can procure one immediately who will be glad of it. No doubt there are many young men who know not where to settle, who would jump at an introduction by a Commissioner for the smallest stipend—almost for nothing—as there are many briefless barristers, of equal talent, who would congratulate themselves at the appointment to the poor-law commission at one-fourth of the emolument the present possessors enjoy; and as economy is held forth as the attribute of the present ministry, I wonder they have not had recourse to this expedient. But no: this would save money to the country, it is true; but it would lessen their patronage, by diminishing the value of one of their numerous commissions.

Should a Commissioner read this, I have no doubt he will laugh at the presumption of a country doctor in giving advice on laws which “work so well.” Truly they do work well for the Commissioners and the rate-payers, but how do they work for the poor? The poor alone can tell; they, miserable creatures, know that they must become beggars, absolutely naked and starved, before they can *claim*, or at least *obtain* any relief, except by the sad alternative of giving up their all, I believe their very clothes, and then their only resource is the workhouse; and when they have once entered that abode, they have no prospect of a return to their cottage, having previously disposed of every article of clothing and furniture.

I should think much might be done for the poor by a tax on the funded property, in the form, for instance, of one-eighth per cent. on every transfer, which might be held for circumstances of peculiar distress in different parts of the country. By this tax many would contribute their quota to the support of

the poor, who now do not pay a farthing. There are thousands who live in hotels, chambers, and lodgings, whose door is never knocked at by the tax-gatherer, nor timidly tapped at by the poor—men with no fixed habitation, but with plenty of money to feed their imagination in the boarding of it, or to squander in personal gratifications.

I know not why the man who possesses one thousand a year in land should pay fifty pounds to the poor, when the fundholder pays nothing. The property of both are equally protected by the laws and military force of the country, the latter of which is drawn almost exclusively from the labouring poor. Moreover, the landowner affords relief to his neighbouring poor in many acts of charity, more especially in time of sickness, which they who live as I have mentioned have not even the opportunity of doing.

I beg pardon for this extra-professional lucubration, and remain, sir,

Yours obediently,

WILLIAM HILL.

Wotton-under-Edge,
Sept. 19, 1837.

MEDICAL GAZETTE.

Saturday, October 7, 1837.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

A FEW WORDS TO STUDENTS.

WITH the exception of underselling schemes in the medical market, the present session seemed to offer so little of novelty, that we did not think it necessary to devote an article especially to it. But since we last wrote, a *sirocco* (or rather, from its general direction, a *tramontana*;) of puffing has blown with unusual violence, and we must give a little advice to those students who have not yet made their arrangements.

Whenever, then, a peculiar advantage is offered, do not let it distract all your attention, but rather search for the ten

disadvantages it is intended to cover. These will not lie deep beneath it. In the majority of instances the pretended benefits are by no means *peculiar*, but are common to all similar institutions. Dr. A., for example, is not the *only* hospital physician who keeps a case-book, nor Mr. B. the *only* surgeon who delivers clinical lectures; nor is clinical instruction the *only*, though when properly conducted it be a very important part, of medical education. It is a system now generally pursued, in degrees of excellence varying with the capacities of the teachers, and often abused, so as to be comparatively useless. The rest of these peculiar advantages are, from the manuscript Baconian communications to the midnight anatomy by gas-light, mere glittering bits of tinsel, as unworthy the attention of the student, as of the character of those who promise them. They are placed in the foreground only to attract the eye from disadvantages for which they cannot compensate.

With this caution, then, to "beware of peculiar advantages," we pass to consider the course which the medical student may best adopt in the years of study he is now commencing. "*Cuique in sua arte credendum*," is more true of the matter than of the value of the subject. If introductory lectures were to be believed, the student would have to try to study each subject to the total exclusion of the others. His head confused by the contemplation of all the magnified glories of each course, placed by its professor in its brightest light, the student resembles Molière's Monsieur Jourdain, in the midst of his masters of music, dancing, fencing, and philosophy, each urging his own especial claims, and his universal utility. And like him, he knows neither how to find time, nor which to choose. We would give him one rule—study nothing except in its immediate practical appli-

cations. The difficulty of studying diseases profitably in private practice, and the impossibility of pursuing some branches of the science, except now, are sufficient to prove the absolute necessity that the student should regard the present as a period during which that knowledge must be obtained which may form the best foundation of private practice, and which future opportunities will be scarcely more than sufficient to retain.

The subject which is above all of the highest importance, is that which has unfortunately been usually regarded as of the least—the clinical study of disease. To it, every thing should be secondary and subservient, and it should be an active and a personal study. It is not sufficient to follow any teacher, however excellent: clinical lectures, if they lead the student to be merely a passive listener, by satisfying him that when he has heard the case read from the book and the accompanying remarks, he knows all that can be learned of the disease, are useless, if not positively mischievous. They offer not the slightest advantage over books to the student who does not himself examine the cases. We do not doubt that these, which many praise as the greatest advantages, are among the worst faults of the French schools: relying on his clinical lecturer, the pupil there seldom touches or speaks to a patient; he takes notes of the examination and the remarks made by the physician, or surgeon, and thinks that he has then sufficiently learned the disease, which by himself he could neither recognize nor treat. This, however, is almost a necessary result of the system of admitting pupils to the wards only during the visits of the medical officers; a system which is imitated in some of our own institutions, and is attended with inconveniences for which no

amount of clinical instruction can compensate. Let students especially look to this: if the wards of their hospitals be not open for them to study disease, quietly and for themselves, they will find it nearly useless to enter them at all. The information to be derived from the lecturer should never be neglected, but alone it is quite insufficient to teach medicine.

We have often observed, that one of the most prevalent errors among students is, that their attendance on London hospitals is rendered peculiarly valuable by the number of operations and rare cases they may see—an error which an abuse of clinical instruction, and the establishment of clinical wards, has not a little tended to confirm. But the reputation and the usefulness of a practitioner will depend chiefly on his ability to cure or alleviate quickly the most common maladies; and it will be of little importance to have seen one or two cases, the *selecta majora* of a clinical ward, which he may never again meet with. Let operations and rarities be the condiments rather than the aliment of his clinical dietetics.

The value of reading and lectures is more than doubled when conjoined with the personal study of disease: the patients may (*magnis componere parva*) be compared to figures or maps, and books and lectures to their letters of reference—the former would require far more labour to comprehend them, without the assistance of the latter, which by themselves are perfectly useless: taken together, it is comparatively easy to learn the nature of the subject examined. In the choice of books, we would strongly recommend the use of monographs on each of the most important subjects, rather than of any one system of medicine or surgery. Even if there had yet been published one which was valuable except for occa-

sional reference, we would still prefer separate treatises, especially after the first year of attendance on practice. They need not be numerous; and even if they were, they would be found much less tedious, as they are also more instructive than single systems, of which the supposed necessity is lessened by the lectures, which, when not marred by the ubiquity of some favourite theory colouring every subject, should completely supply their place. As we have recommended the avoidance of "peculiar advantages," so we do that of *peculiar ideas*; both are most probably alike unsound. In reference to reading, students will do well to regard libraries and reading-rooms attached to their schools as of much value.

The general tendency of our advice on the study of anatomy must be the same. It should be regarded as next in importance to clinical study, not only because it has a most near relation to, and important applications in, both medical and surgical practice, but because the present affords the only opportunity which the majority of students can have of pursuing it. It, too, should be strictly practical: one attentive dissection will teach more, and more lastingly, than many lectures or demonstrations, or than any amount of reading. The latter by itself is perfectly useless, and, besides, so unpleasant a mode of losing time, that it is surprising it should be so much resorted to. In their first year, students should use, while dissecting, some condensed manual, and, as a general rule, that written by their teacher ("as which of them has not?") will be most advantageous. Afterwards, monographs, and the special descriptions of various organs, and the different more minute arrangements of parts and structure, should be studied; but all with equal reference to their practical importance. It need

scarcely be stated, that surgical skill is impossible of attainment without a due anatomical knowledge; much of medical practice is importantly assisted by it, and without it pathology and physiology would cease to exist. Its importance, therefore, makes it highly desirable that it should be studied attentively during the whole period of hospital education; not a day should be allowed to elapse without adding something to the stock of which all memories have so slight a tenure, and which, when lost, it will be so difficult to replace. The opportunities afforded for dissecting and for medical and surgical practice, should be the principal, if not the sole, guides to the student in making his choice among the schools.

We would now proceed to the collateral branches of education; but we must confess, that when we have already recommended daily and attentive practical study in the wards and in the dissecting-rooms, we have given very nearly enough to occupy the whole of the time usually allotted to work; for these would require three hours of lectures, and at least two for anatomy, and two more for the wards, each day; yet there are midwifery, chemistry, botany, materia medica, medical jurisprudence, all to be learned. *Quid agendum?* In the conversations which we have had with numerous students now commencing their studies, it has been lamentable to see how nearly universal the feeling is, that the only thing to be worked for is the passing of their examinations, and especially of that at Apothecaries' Hall. Yet this is neither surprising nor deserving of censure. We need not repeat the reasons why, as we have often shewn that the time allotted is quite insufficient for attaining a proper knowledge of all the subjects required; but as the license is essential, it is striven for at any sacrifice.

We are sorry to recommend any thing like a superficial study of important sciences; but we are compelled to advise students to disregard, during the first years, all that has not an immediate bearing on matters of primary importance, and to make the best use of their time to obtain a sound practical knowledge of their profession. Let them, at least, not waste the winter, when they may be studying anatomy, and watching disease; and let them work up the details of other matters a few months before their examination. We recommend this with the less hesitation, from the conviction of the inutility of a great part of these subjects in practice, and from knowing that, if learned now, they will be forgotten before the examination arrives, in the constant occupation of the mind by other more important studies.

In conclusion, we would strongly urge students not to think that the sooner they can pass their examinations and get into practice the better, but let them devote every day that they can spare, even after they have obtained their diplomas, to the improvement of the opportunities now afforded them. When deprived of them, they will discover, perhaps too late, their value; and the majority will find, to their sorrow, that their day of greatest medical knowledge was that on which they ceased to be students, and became practitioners.

HINTS FOR EXAMINERS.

EXAMINERS would be not a little surprised at the intimate acquaintance which is generally possessed of all their systems, and at the ingenious means which are resorted to to evade their vigilance, or slip through the loop-holes in their regulations. We question whether they themselves know nearly so much about their own laws as those whose interest it is to avoid them. For their information, we beg to present some announcements which this season has produced.

Here is a *morceau* for the Col-

lege:—"Gentlemen prepared, by private instruction, for passing the College of Surgeons, three guineas; during which time, those who have previously attended other schools, are permitted to attend Mr. D.'s public lectures" (on anatomy, and surgery, and demonstrations, all recognized,) "and dissections, and receive certificates of the same gratuitously." Now what does this mean, but that those who have, for any cause, been refused their certificates at another school, may buy them here for three guineas?

And here is a *bonne bouche* for the Hall:—

"Mingaye Syder, licentiate of, and senior private examiner for, Apothecaries' Hall, has continued a collection of notes, from the year 1821 to September 1837, embodying every question of the *least importance* ever mooted at the Hall during that period. To this advantage his method of conveying information, and the facility with which his system accustoms the student to express himself with perspicuity and becoming firmness, Mingaye Syder," &c.

Oh! "Mingaye Syder"—Galen, what a name! And then the "senior private examiner." Hail! thou Nestor of grinders; and the "becoming firmness" and the "perspicuity"—is rhetoric required? is a "*sermo lenis minimeque pertinax*," or "*cum sale et facetiis*," most worthy to be studied? But of all advantages, surely this is the greatest,—all the questions from 1821 to last Saturday night!! But, by the by, this is not peculiar to Syder; several complete copies, we are told, are extant; and a remarkable unity of character is said to reign throughout each. Surely it would be well to commence a new series in October 1837, even at the risk of ruining such valuable members of the profession as the above.

GUY'S HOSPITAL.

HYDROPHOBIA.

To the Editor of the Medical Gazette.

SIR,
PERHAPS the following case may not prove uninteresting to some of your readers; I think it shows the inefficacy of opium as an antidote in hydrophobia. The history of the case is perfectly correct, and was taken by myself while sitting by the

patient's bedside, which I did from the time of his admission till the period of his death.—I am, sir,

Your obedient servant,
FREDERICK CHARLES JONES.

Sept. 30, 1827.

Edward Lynche, aged 26, a strong and muscular man of moderate size, a native of Cork, has been in England for twelve months, and with the exception of periodical attacks of ague, has enjoyed a good state of health. About five weeks ago, while harvesting in Kent, he drove a dog from the barn in which he was living. Afterwards, on going into the fields, he accidentally left the door of the barn open, and two dogs entered. On his return to fetch a knife and fork, the dog which he had previously driven out flew at him, and bit him in the cheek and upper lip: he seized the dog between his knees, and strangled him with a bit of hayband, which he took from his pocket.

The lip, which was much torn, was immediately excised at the wounded part, but, according to his wife's account, nothing was done to the wound of the cheek. A subscription was entered into to facilitate his departure with his wife, who being in the family-way, it was thought best not to inform her of the possible consequences of the accident.

Lynche stated that his habits are temperate, but that on Saturday, the 23d of September, in the evening, he drank two or three pots of beer, after which he was seized with a fit of vomiting, and loathed the sight of meat; he slept well, however, on that night.

On Sunday, at nine in the morning, his bowels were open, but he was very unwell all that day, and in the afternoon fell into a deep sleep, from which there was some difficulty in awakening him. He had no spasms, but passed a restless night.

On Monday morning spasms took place, and he became worse; bowels not open; passed a quiet night; but on Tuesday the 26th, he was taken into the hospital at nine o'clock in the morning, and a bed was assigned him in Billet's ward. At a quarter before ten a turpentine enema was administered, the greater part of which remained in the intestines.

I saw him at a quarter-past 10, one hour after his admission; his pulse was soft, slow, and irregular; he complained of no pain, but a feeling of great lassitude; could drink no water, but took a table spoonful of milk; felt a sense of constriction of the throat: his voice feeble, and when speaking resembles a loud whisper; the skin moderately warm; extremities cold; no perceptible perspiration; pupils

dilated; tongue moist and clean; countenance anxious: on the approach of any one a slight spasm takes place, and he appears as if being choked. Dr. Babington was immediately sent for, and on his arrival at about noon, found the previous symptoms much aggravated. Pulse 60; heat normal; tongue slightly coated, but moist; skin of natural warmth; no pain; chest sonorous upon percussion; respiratory sound natural; breath of an acid odour. Every two or three minutes he was seized with spasm, characterized by violent and gasping efforts at respiration. A high degree of nervous irritability was apparent, and was increased by the presence of visitors, and even by light, so that he kept his head turned from the windows, and his eyes closed.

Dr. Babington, in consultation with Dr. Baek, ordered ʒj. of the carbonate of iron to be given in the form of bolus, every half hour; his spine to be well rubbed with ceratum cantharidis, and a belladonna plaster to be then applied along its whole course. While these means were in preparation the spasms became more frequent, and were excited by the most trivial causes, such as opening a door, the movement of a person about the room, &c., owing, I suppose, to the vibration of the air upon the face. Even flies seemed to cause him much annoyance.

About half-past 2 he sunk into a refreshing sleep, which lasted for three quarters of an hour; the ward door was ordered to be closed, to prevent the patient from being disturbed.

5 o'clock.—He complained of great prostration of strength; the spasms were greatly increased in intensity; the tongue moist; pulse 54, irregular and intermittent; skin rather warm: he felt no pain in the lip, but had the sensation of a ball rising in his throat; when he spoke it was with great exertion, and like a man out of breath; quite sensible. He has passed his urine three or four times, rather high coloured.

7 o'clock.—Getting rather more restless; pulse 84, sharp; tongue dry, mouth parched, skin hot, but no perspiration. The boluses were divided into three, and after each he took about two ounces of milk, which was all the nutriment he had since his admission to the hospital. He had taken five of the boluses, and when taking the sixth he experienced great difficulty in swallowing, in consequence of the flatus meeting the substance passing into the œsophagus. Pulse, while I was writing the above, sunk to 64; he appeared very much convulsed, and could not bear any one to stand before him, but did not mind my standing at his back.

10 o'clock in the evening.—He was

more convulsed; and Dr. Babington, finding that no diminution of spasm had resulted from the use of carbonate of iron, ordered him three grains of muriate of morphia every half hour till a mitigation of the symptoms should ensue; and that, in addition to the plaster down the spine, his breast and the region of the diaphragm should be rubbed with ceratum cantharidis, and a belladonna plaster applied over the stimulated part. Pulse 54, but rather full. He was more restless; could not bear to have the candle brought into the room; his voice, however, was more natural, and there was no rigidity of the muscles. His cries were loud and frequent, and he did not like any one but his wife to come near him.

At half-past 10 he took three grains of muriate of morphia in the form of pill, and was getting more restless.

At 11 he took three grains more; the former dose appeared to have given him some relief, and he was becoming more composed. Slept till 3 A.M. on Wednesday. At half-past 3 he was rather restless, and the dose was repeated.

5 o'clock.—Passed a quiet night upon the whole, crying out, however, at intervals. Pulse 68; described himself as better, but rather sick. He took a cupful of milk, which he asked for himself, but swallowed with great difficulty. Bowels not open since his admission.

7 o'clock in the morning.—Getting more restless; pulse 80; tongue dry and furred; made water freely; skin hot, but no perspiration; said he felt no pain, but felt a weakness at his heart.

8 o'clock.—Asked for some water; took two ounces, but immediately jumped up in bed, and appeared choking. The pupils were contracted; spasms more violent. Repeated the dose of morphia.

10 o'clock.—Was very violent; and when Dr. Babington entered the room, jumped out of bed in a frantic manner, yet apparently without any definite object. No persuasion could induce him to return, till at length he promised to do so if left alone. The experiment was tried, but no sooner had all parties retired than he bolted the door, made a rush at the high wooden railing which separated him from the windows, and, before an entrance through another door could be gained, thrust through two squares of glass over the railing which he had forcibly torn away. His wife (who had not long quitted him) now arrived, and succeeded in inducing him to return to bed. To avoid future accidents to himself or others, since he was evidently growing more unmanageable, it was thought necessary to secure his arms and legs, which were fastened to the bed by means of sheets. The confine-

ment excited him much at first, but he gradually became reconciled to it. He was particularly anxious, however, that only one person should enter his room at a time. Dr. Babington ordered him an additional grain of muriate of morphia every half hour.

11 o'clock.—Tongue parched; skin moist; pulse 86. Had had no stool; bellowed out very loudly, in a deep hoarse voice; after each paroxysm he became very low; his countenance was expressive of great anxiety, and his manner extremely irritable. He was decidedly much worse.

Half past 12.—Still keeps crying out, and asks for milk, but cannot bear the sight of the cup, which he directs may be kept under his bed. The fluid makes him sick, or rather is forcibly ejected from his gullet. He has had two doses of 4 grs. of muriate of morphia, and is now taking 8 grs. more; which Dr. Babington has ordered to be repeated every half hour, until a decided control over the paroxysms is established. Skin moist. He is to have a tobacco enema exhibited as soon as possible. The voice is becoming more thick, the breathing more laborious, and the feeling of oppression much increased. The pulse 140 after the paroxysms, but he expresses no more horror of fluids than of any thing else he is requested to swallow. An apple was offered him, and he bit a piece from the side, but was unable to masticate it.

A quarter before 2.—The angles of his mouth continually elevated and depressed; eructation, accompanied by a noise having a slight resemblance to the howl of a dog; very much convulsed; countenance very livid; eyes having an up-turned expression; breathing about eight times in a minute; pulse 180, small; contraction of the occipito-frontalis muscle; chest heaving; breathing very laborious; changing rapidly for the worse. Tobacco enema cannot be administered, on account of his violent spasmodic movements. His lower extremities were confined in the same manner as his arms. Pulse hardly perceptible; appears perfectly unconscious of what is taking place, but seems to have some ideas of a pleasing nature, for now and then the countenance assumes a serene smile, evidently not owing to convulsive contraction. Pupils strongly contracted, and not obedient to light; conjunctiva much injected.

2 o'clock.—Dr. Babington sent for. Pulse 195; twitching at the bed-clothes, and pulling his neck about very much. All the bad symptoms considerably augmented. From this time till the period of his death, which took place at twenty minutes past 3 in the afternoon, his pulse was continually varying. He died coma-

tose, and immediately after death his pupils were observed to be very much dilated. On attempting to obtain some blood from the arm after death I failed. Some serum flowed about half an hour afterwards, and in the course of three or four hours the sheet was found saturated with blood.

ST. BARTHOLOMEW'S HOSPITAL.

Morbid alterations in the Articular Tissues from Chronic Inflammation.

Aug. 17, 1837.—The knee-joints removed by amputation from two patients on the 15th, were examined, after having been injected with size and vermilion, and presented some points of interest in relation to the changes induced by long-continued inflammation in the several articular tissues.

The symptoms during life had clearly indicated chronic inflammation of the synovial membrane as the primary disease, upon which ulceration of the cartilages, elongation of the ligaments, and suppuration and ulceration around the joints, had supervened. In one case (that of the child) the disease had lasted for nearly two years; in the other (a man of 32) for fourteen months. The morbid appearances in both were almost precisely similar.

The ligaments were softened and lengthened; they had lost all that density and that peculiar wiriness of feeling which they present in a healthy state, and they could be pressed out between the fingers, or scraped into a fine membrane. The external lateral ligament was merely lengthened as it extended over the swelling, but preserved its rounded form; while the internal, besides being equally lengthened, was expanded like a membrane over the thickened subjacent tissues. The crucial ligaments were torn across with but little effort, in separating the heads of the tibia and femur.

The synovial membrane was in some parts at least half an inch in thickness, and presented a soft pulpy reddish surface, lining dense fibrous and gelatinous layers. This change had affected it in its whole extent, and where opposite surfaces similarly altered had met, adhesion had taken place, and the cavity of the joint had there been obliterated. In many parts, similar pulpy matter was effused upon or beneath the synovial membrane covering the cartilages on the heads of the bones, presenting the same reddish vascular surface, and here and there united to the adjoining similarly altered parts. The vessels of that part of this deposition

which lay upon the cartilages, were evidently derived from the synovial membrane around their edges, and did not pass from the bone through the cartilage, which beneath many of these spots appeared quite healthy.

In addition to the changes above described, as found on portions of the articular surface of the cartilages, these were in several parts completely removed by the absorption which highly vascular granulations, arising from the subjacent bone, had effected. In some small spots, these granulations protruded through holes which they had made in the cartilage, and presented bright red, fungous-looking papillæ, projecting into the joint. Where they had grown to a less extent, the cartilage was as it were undermined by them, and could, for some distance, be stripped off with the greatest ease. In one of the joints the cartilage had been completely removed from the inferior and posterior part of the condyles of the femur, at the part where, in the bent position of the limb, it had been in contact with the upper surface of the femur, and here a firm, very hard, polished surface of bone presented itself.

In the limb of the adult the bones had retained their natural structure, except in the part immediately adjacent to the cartilages; but in the boy's leg they were highly vascular, and their walls were considerably thinned: this was rather singular, because almost the only difference in the symptoms had been, the far less degree of pain which the boy had suffered for several months than the man had.

A few days afterwards a knee-joint was obtained after death, from a young woman who had died of phthisis. It had evidently been affected some years since with morbid processes, in some respects similar in character to the above, but had been long since cured, for, except in partial stiffness, and a slightly flexed state of the limb, no outward appearance of disease existed. The ligaments were healthy, and of their proper length and firm texture, and the synovial membrane was but slightly thickened. Many large patches of cartilage were completely removed. In the preceding cases it had appeared as if the pressure on the opposed surfaces on the heads of the bones had induced an early absorption of the cartilage at those parts; here, however, it was perfectly sound in these situations. In the parts where it was removed entirely, a thin filamentous cellular tissue was found on the surfaces of the bones, where they were in contact with synovial membrane; while in the other case, where the bones had come in contact with each other, they had assumed a smooth surface and an ivory hardness. In

some situations the same cellular tissue extended on to the edge of the cartilage, and firmly adhered to it, but it could not be seen if vessels passed from one to the other. The slighter degree of alteration in the synovial membrane over the cartilages, shewed very clearly the important modification which is induced in the effects of inflammation in the same tissue, by differences in those subjacent to it, and from or through which it receives its vascular supply; while the difference observed in the surfaces of the bones as they were in contact with each other, or with the synovial membrane, presented an analogous instance of the effects which external circumstances have on the products of an exposed and inflamed surface.

Singular Production of Urticaria.

In the stomach of a horse, which had been brought in the morning from the knackers for a preparation, there were found a number of large lumbrici. As two gentlemen were endeavouring to inject the intestinal tubes of some of these with mercury, one of them was seized, about five minutes after he had commenced handling the worms, with a violent fit of sneezing, accompanied by a profuse flow of mucus in the nose, swelling of the Schneiderian membrane and integuments, so as to be evidently visible externally. These symptoms were soon followed by an eruption of nettle-rash over all the face and neck, with the most intense itching and heat, which increased as the irritation about the mucous membrane of the nose became less. After about ten minutes the eyelids swelled and became œdematous, the conjunctiva was reddened, and a considerable secretion of tears took place. Then the eruption appeared on the hands, and soon after, in a slighter degree, over the arms and chest. The annoyance continued extreme for nearly an hour, and the itching and redness from the urticaria did not disappear till five or six hours after it first commenced.

The other gentleman was affected in precisely the same manner, about a quarter of an hour after he began to attempt the injection; but in him the symptoms were less severe, perhaps from his being in the habit of taking snuff: none of them, however, were absent.

Nothing but the effluvia from these lumbrici, which were somewhat evident by a strong rank smell, could have produced these effects; no putrid matter of any kind was lying near, and the two persons simultaneously affected had not been exposed to any other common cause that could have led to it; indeed, they had not been together for ten minutes before the affection commenced.

WESTMINSTER HOSPITAL.

Case of Impervious Stricture—Newly-modelled Operation.

R. SHEPPARD, about 50 years old, was admitted, under Mr. Guthrie, on the 16th June ult., with stricture, of long standing, in the urethra: he had frequently been attacked with retention of urine, which had always been relieved by the warm bath. The stream of urine had been scanty for many years.

On the 25th, a few days after his admission, he was attacked with a paroxysm of retention. He was placed in the warm bath for half an hour, and a strong dose of castor oil and a drachm of Battley's opiate solution were given to him. Whilst he was in the bath, an attempt was made to pass a catheter for him, but without effect. But being easier, though not relieved of his urine, he was put to bed: he slept quietly till six the next morning. He then became uneasy, and was again placed in a warm bath, the pain being relieved, but no urine could escape.

At 1 P.M., 26th, the patient had great anxiety of countenance; the bladder reached to the umbilicus, and the perineum was tumefied and painful. There was much fever. Mr. Guthrie endeavoured to pass a catheter, but did not succeed. He then had applied twenty leeches to the perineum, and fomentations to the abdomen, and a clyster of laudanum and gruel was thrown up into the rectum. These measures produced temporary relief.

At 6 P.M. all the symptoms were aggravated, and Mr. Guthrie in consequence determined to operate. The patient was placed on the table in the position proper for lithotomy. The surgeon introduced a catheter (No. 8) as far as the stricture, and an assistant firmly held it in that position. Mr. Guthrie now placed his left index finger in the rectum, and ascertained the exact seat of the stricture. Retaining his finger in the stricture, he made a transverse incision in the perineum, an inch and a half above the anus, and cut through the several fasciæ to the seat of the stricture, which he divided; he then passed on the catheter into the bladder, and drew off three pints of urine, of which the last portions were highly ammoniacal. The patient was relieved, and the wound being dressed, he was put in bed, and an opiate was given to him.

27th.—The patient had a good night. He is quite easy, and the urine flows through the perineum as well as along the urethra.

28th.—He had a good night without opium; this morning pain in the penis

came on, and all the urine came through the perineum. In the course of the day the symptoms were aggravated. In the evening the penis was swollen and painful, and he had thirst, anxiety, and heat of skin. His bowels opened with castor oil. Fomentations were used, and an opiate subsequently administered.

29th.—The opium gave him a good night, and he is quite easy. His countenance is tranquil; his pulse 98, and soft; he passes his water partly through the urethra and partly through the wound. Twenty leeches are applied to the perineum.

30th.—The scrotum being tumefied and painful to the touch, and the patient having severe pain in the testicles and perineum, Mr. Guthrie made two small incisions in the scrotum, and let out some pus. No urine flowed from the wounds.

July 1st.—The pain of scrotum is less, but the penis is more swollen. The penis is therefore scarified all over, and relief is afforded.

2d.—He had a good night's rest. This morning the penis is more swollen, and a black slough has made its appearance in the integuments of the penis, on the under surface of the organ, about two inches behind the perineum: the slough enlarged, and nearly surrounded the penis like a broad belt. Mr. Dasent made two incisions through the integuments lengthwise, along each side of the penis; about an ounce of blood flowed. Fomentations applied to the inflamed surface.

4th.—The patient is much better. The slough (as large as a crown) has separated.

Sept. 2d.—The cicatrix formed by the loss of the slough has contracted, and the penis is consequently distended during priapism. A gum elastic catheter (diameter, No. 9,) is introduced in order to provoke the absorption of the stricture.

6th.—The catheter is withdrawn to day, and the patient is able to make water in a stream of moderate size. There is still some slight irritability of bladder, the patient being obliged to get up three or four times in the night for the purpose of micturition. His health is good.

Mr. Guthrie observes upon this operation—"The improvements which have been made in surgery of late years, render this operation less necessary than formerly; cutting out and cutting into portions of the urethra, are, like cutting out testes, comparatively obsolete operations; but still an opening into the urethra may occasionally be required, and when the disease is situated at the termination of the bulbous portion of the urethra, or further back, I recommend the operation to be done in the following manner:—The pa-

tient being placed and secured, as in the operation for stone, a sound is to be passed down to the stricture and held against it; the rectum having been previously cleared by an enema, the index of the left hand is to be introduced into it, and the membranous part of the urethra and the prostate are to be examined, as well as the bladder. If the membranous portion be dilated with urine, so much the better; but the object of introducing the forefinger is to ascertain the relative situation of the upper part of the rectum and the urethra, which latter organ only touches the rectum at the termination of its membranous portion and the commencement of its prostatic portion. There is a certain distance, which is greater or less in different individuals, between the last inch of the rectum and the urethra placed above it. The two parts form two sides of a triangle; the apex of which is the prostate, the base the external skin. It is within the two lines of this triangle that the operation is to be done. The surgeon taking the catheter in his right hand, whilst the forefinger of the left is applied to the upper surface of the rectum, moves the point upwards and downwards, so as to communicate with the forefinger of the left hand, and to convey to it a knowledge of the situation of the extremity of the instrument, and particularly of the distance between them; which the motions given to the catheter by the right hand will clearly indicate. The next step of the operation is to divide the skin, cellular membrane, fascia, and muscular and tendinous fibres, which intervene between the rectum and urethra. There are two ways of proceeding: the first, when the obstacle is behind the bulb and the exterior parts are not diseased, may be commenced by a straight incision in a perpendicular direction. If the surgeon be not well acquainted with the anatomy of these parts, or if they are very much hardened, a transverse curved incision should be made across the perineum, about a quarter of an inch above the verge of the anus. This gives room. If the transverse incision be not adopted, the point of the straight bistoury is to be placed on the skin, a little above the verge of the anus, the cutting edge being above and the back towards the rectum, the handle a little depressed, and the apex directed upwards a little. The knife is to be carried for the distance of an inch in this direction, and clear of the rectum; it must then be carried upwards, and brought out in the median line, making a division of the external parts to the extent of an inch and a half. The part being sponged, the surgeon again introduces the bistoury in the median line, and deepens the cut, being guided by the touch of the

forefinger in the rectum. He then feels for the urethra with the right index-finger, an assistant keeping the catheter steady against the stricture, the end of which will now be readily felt. If the forefinger of the right hand does not go beyond it and touch the sound part of the urethra, the knife is to be resumed, and the urethra to be exposed and opened, which may be done at the apex of the prostate. Whether the stricture be now divided or not, the cure may be completed under either predicament."

Supposed case of Poisoning.

Hannah Mayes, a beautiful creature, about twenty-three years old, known as a respectable servant girl, was admitted the 16th September ult. When brought in, she was in a state of insensibility, which had existed sixteen hours. By the friends' account, this had been preceded by a fit of epilepsy, which she had been subject to for years. She presently came to herself, but, in about ten minutes afterwards, she had another fit of these hysterical epileptic or anomalous paroxysms.

As long as she lived, these fits occurred at short intervals of about ten minutes. The force and frequency, however, of the attacks diminished in proportion as the patient became exhausted, and she ultimately sunk in the course of a few hours, apparently worn out by the abnormal muscular efforts. During the intervals of intermission the countenance of the patient was placid, the face flushed, the palpebræ closed, pupils contracted, respiration short and frequent. A pyramidal tumor occupied the lower regions of the abdomen, inferred to be the pregnant uterus. In this part auscultation indicated the presence of foetal pulsation. The pulse of the patient was about 90, full and soft.

When the fits came on, the respiration was accelerated to 50 per minute. The facial muscles were first affected, producing by their unnatural contraction most painful mal-expressions. The voluntary muscles of the trunk and limbs were then excited, especially all those parallel to the spine. The spasms induced in these last muscles were occasionally of so tonic a character, as to produce an appearance of opisthotonos. The veins of the face and head became distended to the utmost of their capacity, and the pulse first became accelerated, and then irregular and inappreciable.

Somebody fancying that the pyramidal tumor was the bladder distended with urine, a catheter was introduced, and three drops of urine drawn off. A blister was applied to the chest; aloetic and colochin-tine purges were administered; the cro-

ton tiglium was placed on the tongue; but harassed nature answered not to these experiments, and gradually yielded to the grasp of death.

Some months previously she had listened to "the voice of the charmer," and become pregnant. To conceal the fact she left her situation, and took an obscure lodging in a low neighbourhood. She thus escaped the observation of her friends. She is said to have exhibited great depression of spirits as her pregnancy advanced, avoiding society, and indulging in hermit-like moodiness. Her mind was obviously tormented by a sense of the disgrace she has incurred; her appetite in consequence fell off, and she ate but very little for weeks. At last the symptoms described occurred; and the question to be decided in a medico legal point of view is, whether the morbid phenomena have been produced by drugs, administered with a view to her own destruction or that of her infant; or whether a naturally sensitive mind, deeply affected with a continuous grief, and acting upon a debilitated body, may not have engendered the suicidal symptoms which have been related. Surely the last supposition does not indicate a principle unprecedented in the moral history of man.

The body was examined twenty-eight hours after her decease. There was turgescence of all the blood-vessels of the brain; the cortical substance evinced a deep pink colour. No effusion into the ventricles had taken place. No tumor, or other abnormal growth, existed in any part of the encephalon. The lungs were congested to such a degree as to present an appearance of consolidation. No traces existed of bronchial inflammation; but the mucous membrane of the pulmonary viscera exhibited a reddish tint throughout: the secretions in these tubes were healthy, as regards both quantity and quality.

The stomach was filled with a bile-tainted fluid, as well as in fact the whole intestinal canal: no trace of disease could be made out in these tubes. A few patches of ecchymosis existed along the great curvature of the stomach; the contents of this viscus were subjected, by Dr. Barham, to a systematic analysis, and his report is, "That a careful application of all the usual reagents affords no evidence of any metallic substance existing in the fluid subjected to analysis."

The annals of hospitals afford not unfrequent examples of such catastrophes as the one just recited,—instances in which every-day events give rise to quiescent passions of a life-destroying intensity.

FEES AT UNIVERSITY COLLEGE.

MR. ATKINSON, of University College, has called our attention to the circumstance of the amount of fees for the lectures required by the College of Surgeons and Society of Apothecaries having been over-rated in the table which we published last week. We have in consequence made the necessary corrections, and re-published it on the wrapper of the present number. The general total being correct remains unchanged, and the School still in its place at the bottom of the list, being, whether for unlimited attendance, or that required by the College and Hall, considerably the most expensive in London.

THE LATE MR. BROUGHTON.

A VERY curious letter, by some one signing himself "A Friend of the Deceased," has been addressed to the Editor of the *Times*, to inform him that the account of the late Mr. Broughton, copied from this journal, was altogether erroneous, and that his death might be called "accidental," having arisen from a vein taking up some pus, which it carried "to the centre of circulation." These and other expressions prove the letter to have been written by some unprofessional person, and it would, therefore, be unreasonable to expect that he should know much about the case in a medical point of view. As to the rest, while professedly correcting, he inadvertently confirms our account in a very remarkable manner. Our information was derived from a gentleman on very intimate terms with Mr. Broughton, who visited him between the performance of the operation and his decease, and who saw the will to which we alluded. The only error of the slightest importance into which we fell was that, in speaking of "Cooper," we supposed he had meant Mr. Cooper, whereas it was Sir Astley who attended. If the writer in the *Times* be really "a friend of the deceased," we can only say he is a very injudicious friend.

NEW MEDICAL WORKS.

Traité de Physiologie, considérée comme science d'observation. Par C. F. Burdach, Professeur à l'université de Königsberg. Traduit de l'Allemand par A. J. L. Jourdan. Vols. 1, 6, 7, 8, are out: the others will appear in three months. Baillière.

Traité des Maladies des Reins. Par P. Rayer. 1ère Liv. grand, in-fol. containing five coloured plates. This work will be completed in 12 Livraisons. Baillière.

The Edinburgh Dissector, or System of Practical Anatomy; for the use of Students By a Fellow of the Collège of Surgeons in Edinburgh.

Guy's Hospital Reports, No. V. Oct. 1837.

INTRODUCTORY LECTURES.

WE have to apologize to those gentlemen who have requested us to publish their Introductory Lectures, for declining to do so: their interest is very much confined to the pupils and friends of the Lecturer.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Oct. 5, 1837.

William Maw Tronsdale, Sheffield. — James Michael Knapp, Minthead, Somerset. — John Kersley, Lipscomb, Alresford. — James Musgrave Gane, Frome. — John Parsons, Goathurst, Bridgewater. — Eli Vickop, Blackburn. — George John Amsden, Huxton. — Thomas Browne, Walden, Essex. — James Liddlerdale, Hungerford, Berks. — Robert George Broxholm, Sunbury, Middlesex. — Thomas Keele, Bristol. — Thomas Jones Dyke, Merthyr Tydfel. — Henry Umpleby, Armin, Yorkshire.

METEOROLOGICAL JOURNAL.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

BY CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE III.

Vital relations of Respiration—Respiration an instinctive action—Its relations to the Nervous System—Nerves of the Lungs—Nerves of the Muscles of Respiration—Mutual dependencies of the Lungs, the Nervous System, and the Heart; illustrated by a Diagram—Asphyxia, its causes and pathology—Why the Circulation ceases in Asphyxia—Dr. Alison's Experiments—Succession of Death through the Organs—Hybernation—Various effects of Cold on the Functions.

WE have thus briefly surveyed the mechanism and the chemistry of respiration; it now remains for us to consider the function in its vital character—the relations in which it stands to the peculiar attributes of life—and why it is so essential to the life of the body at large. What is the cause which determines the respiratory movements? Is it something inherent in the muscles concerned; or are their actions dependent on a sensation, or other stimulus of the nervous system? Is respiration a voluntary or an involuntary act? How is the act excited first in the newly-born infant? Such are some of the questions that have occupied the wits of

great physiologists of many ages. They shall not detain us long. Time will not permit us to run through the diversified answers which successive authors have given to these questions; it will be enough to develop that which, as the most consistent with physiological, and especially pathological facts, will be most useful to us in our subsequent allusions to the function as related to life.

That respiration is not, properly speaking, a voluntary act, is obvious, inasmuch as it usually takes place without any act of the mind, even in coma and complete stupor, when the mind is incapable of willing. But we know, also, that we can at pleasure control respiration; we can increase it, quicken it, and for a certain time stop it. All the muscles of respiration are, therefore, subject to the will, although acts of volition are not necessary to their regular action. What is it, then, that excites them in this regular action? We may find out, by trying to its utmost the power of our will to stop respiration. We stop our breath for a little while by a direct control of the muscles of respiration; but soon we feel a sensation of oppression, which irresistibly throws these muscles into action; and the only way in which we can still stop our breathing is by closing the glottis, and keeping the diaphragm pressed upwards by the contraction of the abdominal muscles. In the course of a few seconds, however, the sensation of uneasiness in the chest becomes intense, the respiratory muscles make violent efforts, and the voluntary act which stops their play is soon conquered by the sensation becoming insupportable. It is stated by some writer on legal medicine, that a man once intentionally put an end to his existence by holding his breath; but it is not likely that the death was one of simple asphyxia, because the mental act of holding the breath could not continue when that mental stupor, that *defectio animi*,

came on, which always precedes this kind of death. But, as we shall afterwards see, the act of holding the breath causes such congestion and obstruction in the circulation, as might readily lead to a fatal result by other ways, such as hæmorrhage in the lungs, syncope of the heart, or apoplexy, in those individuals who are predisposed to these affections.

I would, with Dr Alison, class the action of ordinary respiration among those which are called instinctive, as being excited by an impression of which, in its ordinary degree, the mind is not conscious. Of exactly the same kind is the action of the eyelids in winking; but similar instinctive motions, equally unattended by any distinct volition, are excited in other voluntary muscles, by particular impressions or sensations—as vomiting by a certain degree of nausea, or by tickling the fauces; laughter by tickling under the armpits; the rapid withdrawing the hand or other part from fire burning, or any thing else severely paining it; and the very action of taking a breath on the sensation of sudden cold applied to the face or surface. The great distinction between these instinctive acts and those which are voluntary, is, that instinctive acts, however complex, are uniform in all individuals, and perfect from the earliest age; whereas the simplest voluntary acts which are preceded by a mental process, vary in different individuals, are imperfect at first, and require practice and education to make them perfect. Thus the child breathes well at first, but does not walk or talk well till after long practice. The sensation which prompts the respiratory act is one which remains after common sensibility ceases, and when the mind gives no sign of activity, as in coma, or in profound sleep; and it has been proved by the direct experiments of especially Legallois and Flourens, that of all parts of the nervous centres, the medulla oblongata is alone essential for its continuance. The brain and cerebellum may be removed without stopping it; but whenever the medulla oblongata is removed, or materially injured, respiration immediately ceases. So respiration is stopped by those influences which destroy sensibility; but it requires a greater degree of them than that necessary to destroy common sensibility, the sensibility which prompts the respiratory act being one of the last to abandon the body. Thus opium in a large dose first throws a person into that state of stupor in which he is insensible to common pain, pinching, &c., but he breathes still. He breathes, it is true, in a laborious and imperfect manner; and although the impression which is acting on the remaining sensibility must be of a very intense kind, it becomes power-

less as this is lost; and the respiration then ceases. A similar result is produced by apoplexy, or any injury which presses on or hurts the medulla oblongata. In apoplexy the pressure is more or less general on parts of the brain connected with common sensations, and these go first; whilst, if the pressure is considerable, the sensibility connected with respiration follows, as in the case from opium. But in direct injuries to the medulla oblongata, or upper portion of the spinal marrow, as where the neck is broken, respiration is destroyed from the first, and death is immediate. But the effect of these injuries or influences may be twofold: it may paralyse those nerves which give sensibility to the lungs; and it may paralyse those motory nerves which convey to the muscles of respiration the stimulus of the sensation or impression; and this brings us more closely to the relations which subsist between the lungs and the nervous system.

The nerves of the lungs (to which I did not advert in speaking of the mechanism) are from the eighth pair, or par vagum. These nerves, just before they enter the lungs, inosculate with the great intercostal; but, according to Reisseisen, the par vagum is the only nervous trunk distributed on the lungs.

Now the eighth pair appear to be nerves of motion as well as of sensation. Their sensitive function we have already dwelt on; and we find in the bronchial muscles, and especially in those muscles which open the glottis at the moment of inspiration, and are supplied by the recurrent branch of the eighth pair, the objects for the motory office of these nerves. The share which this nerve has in transmitting to the sensorium the impressions which excite the muscles of inspiration, was manifested in some recent experiments by Dr. M. Hall and Mr. Broughton, in which pinching the nerve was immediately followed by an effort at inspiration; and that this does not depend on the motory functions of the nerve, is obvious from the fact, that the same effort is excited when, after the division of the nerve in the neck, its upper segment only is compressed, which is exactly what occurs with nerves of sensation, while the contrary happens with motory nerves. The division of this nerve does not at once destroy the sensibility on which the respiratory movements depend, but it greatly impairs it; for mechanical irritation of the bronchi will not then excite coughing, and expectoration consequently ceases. Another effect of the division of the nerve has been noticed by Mr. Swan, namely, that the air which is introduced into the lungs in inspiration, is not duly expelled by expiration, and, accumulat-

ing in the cells, causes a certain degree of permanent distension. This implies a degree of paralysis of the bronchial muscles, the contraction of which we have before noticed as a part of the forces which complete the act of expiration, not as being of much force in itself, but as equalizing and aiding the diminution of the volume of the lungs, which is mainly effected by the pressure on them of the diaphragm, and of the parietes of the chest. I would beg your attention to a circumstance which seems to shew that this incomplete expulsion of air is also to be greatly ascribed to a loss of sensibility in the bronchial membrane.

If, after an ordinary expiration, we hold our breath until the sensation in the chest becomes painful, and then breathe, the first act is usually a quick, but short expiration, followed by a deep inspiration, as if the lungs were even more anxious to expel the remaining foul air, little as it is, than to draw in pure air. When we hold our breath after inspiration, the disposition to expire air is of course much stronger; and the act of merely breathing out a little slightly relieves the sense of oppression, and enables us to hold on a few seconds longer without taking in more air. These things seem to imply that the bronchial membrane is irritated by the presence of foul air, and seeks to get rid of its presence, both by the contraction of its own muscles, and by exciting those distant muscles concerned in expiration, which instinctively obey the peculiar sensation or impression which is present. It is not unimportant to notice these circumstances, as shewing that expiration is not merely mechanically necessary to prepare for inspiration, but that it is also a vital action under the influence of its own sensibilities and corresponding forces, as we have seen with respect to inspiration.

We have seen that the division of the eighth pair in the neck, although it greatly impairs respiration, does not arrest it; and a sufficient explanation of this may be found in the innervation of these nerves with the intercostals, through which the impression which excites the respiratory act may still, in a certain degree, be transmitted to the medulla oblongata.

The relations between the lungs and nervous system that we have hitherto considered, are chiefly those of sensation; but there is an indirect relation between the lungs and certain motory nerves, which is equally important in maintaining the circle of communication between the lungs and the mechanism by which they are filled and emptied. The chief motory nerves supplying the muscles of respira-

tion are the phrenic, which go to the diaphragm, the intercostal twigs of the spinal marrow to the intercostal muscles, the spinal accessory nerve to the sternomastoid and trapezius, the external respiratory to the serratus magnus, various of the cervical nerves to the scaleni, and other muscles more or less concerned in raising the thorax. It has been found by experiment that the section of these several nerves, or of the spinal marrow above their origins, suspends the action of their respective muscles in the respiratory movements. There are, besides, some motory nerves which co-operate, not through muscles which alter the capacity of the chest, but through those which keep open the canals through which the air passes into the chest. Of these the recurrent branch of the eighth pair supplying the crico- and thyro-arytenoid muscles which keep open the glottis, and the portio dura of the fifth pair, through which the nostrils are dilated, are the chief; and of these it has also been found by experiment, that a section of the nerves prevents the free opening of the respective passages. Dr. H. Ley has pointed out pathological facts which illustrate the same point with regard to the recurrent nerves, in the case of spasm of the glottis from tumors under the upper part of the sternum compressing these nerves, which generally antagonize the superior laryngeal nerves which influence the muscles closing the glottis.

The various motory nerves concerned in respiration, may be excited by other sensations besides that from black blood and foul air in the lungs: thus cold water dashed on the face will cause a deep inspiration; tickling the nostrils will cause sneezing; irritating the glottis, coughing; pain, sobbing, &c. We avail ourselves of these sympathetic associations of nerves and muscles to excite respiration in new-born infants, and to restore it in cases of suspended respiration. That there is sufficient ground for constituting these various motory nerves into a system distinct from those which move the muscles in obedience to the will, as supposed by Sir C. Bell, is very doubtful; and the reason assigned by him for their exciting and combining the respiratory movements, that they originate exclusively from the lateral columns of the spinal cord, from which also the great sentient nerve of the lung, the eighth pair, arises, is, as Dr. Alison remarks, by no means established. It would be easy to prove, by a reference to the anatomy and functions of the nerves, that two nerves arising from one root do not necessarily act in concert. We must, therefore, add that the reason of the concert is not explained; but its cause, its object, is

obvious, as Sir C. Bell himself observes, in the nerves and muscles employed to aerate the blood, "being put under the guidance of a sensibility more certain and more powerful in its effects than the will."

There is thus made out this double relation between the lungs and the nervous system—that of *sensation*, acting from the lungs to the medulla oblongata; that of *motion*, from this nervous centre, through various nerves, to the muscles of the chest which move the lungs. The diagram given further on exhibits these relations. That there are, besides these, other *occasional* relations between various parts of the nervous system and the lungs, capable of *influencing* the functions of the vessels of the latter, is very probable; but that these relations are constant, or in any way necessary to the function of respiration, or to the nutrition of its organs, as supposed by Dr. Wilson Philip and others, is a matter of mere hypothesis, unsupported by any unequivocal fact, and rather opposed than otherwise by the known attributes of the nervous system. It might be interesting, but I doubt that it would be profitable, for the purposes of these lectures to enter further on these matters.

We have thus seen how the function of respiration hangs, as it were, on that of the nervous system: we have now to trace the converse link—how the nervous function is also dependent on respiration. This link, most important in itself, and equally important in spreading the effects of respiration through the system, is constituted by the heart and the double circulation connected with it. All that we learn from the mere mechanism of the heart and its sets of tubes is, that it is admirably adapted to carry the blood in one direction—from the right auricle to the right ventricle, from the right ventricle to the pulmonary artery, which subdivides again and again until its branches are of that size which constitutes the capillary bloodvessels of the lungs. These form a network around the air-cells and minute tubes, from which network the many smallest branches of the pulmonary veins arise, which unite into fewer larger ones; these, again, converge into the four pulmonary veins which bring back the blood to the heart, now entering the left auricle; from this it passes to the left ventricle, and thence is distributed by the aorta and its various branches throughout the system. These branches subdivide, until, as in the lungs, they form the capillary network, from which again arise the veins, which converge into trunks; all these unite in the venæ cavae, which, entering the right auricle, completes the circulation. All this course is plain from the mechanism of the

valves of the heart and veins, and can be imitated in the dead body, by injecting liquids through the vessels. This is the *hydraulic* apparatus of the circulation, and, as such, it is regulated by hydraulic laws, which deserve their share of our attention, and will be further considered in the third part of this course, when we come to treat more particularly of the heart and great vessels.

But we have now to think of the vital properties that are added to the mechanism, the contractility of muscular fibre, and the relations in which that contractility stands to the quantity and quality of the blood that excites it, and the relations which subsist between it and the nervous system, which can influence it. We have also to think of the blood, not merely as an inert liquid, passively propelled through pipes, but as a liquid teeming with chemical and vital properties, which are continually acting on the vital properties, and, through them, on the mechanical powers, of the various solids through which it passes. Between all these properties there are certain relations or proportions which may be called healthy or natural, inasmuch as they tend to support each other with such an even balance as leads to durability and permanency. Thus, for the proper or natural action of the heart, its right cavities should receive a due supply of venous blood, which being their proper stimulus, excites them to propel it into the pulmonary artery; its presence there excites, in the nervous system, the impression which leads to the movements of respiration; these, by bringing the air to act on the blood, renders it arterial, and thereby fitted to return by the pulmonary veins to the left cavities of the heart, of which, thus arterialized, it is also the proper stimulus; from these it is propelled through the various arteries to all parts of the body, of whose functions and textures it is the proper support and pabulum. Among these parts which thus require the supply of arterial blood, are the substance of the heart itself, which thus supports its own function, whilst its function is necessary to effect this support: the nervous system, which as it is necessary to maintain the function of respiration, so in receiving arterial blood it becomes through the heart dependent on that function; and the muscles of respiration in like manner depend on their own work through the heart, which supplies them with its product. Thus is the chain of mutual connexion and dependence complete, and it may be seen in this diagram how any break in this chain must destroy the order of the whole arrangement, and arrest that circulation of influences which is the characteristic of life.

THE CHAIN OF LIFE.

The dependence of the heart on the nervous system through the lungs, is sufficiently plain in this diagram; but you may see that there is an attempt also to represent that the action of the heart is otherwise independent of the nervous system, although it may be influenced by it. Thus the nervous system hangs on the heart for its supply of blood; but the heart hangs on the nervous system only through its link with the lungs. Substitute for this link artificial respiration, and you may then *quietly* cut away the nervous system without disturbing the heart's action. But if you do *violence* to the nervous system, you may shake and disturb the heart also. You may find this diagram useful in studying the causes of asphyxia, syncope, and other kinds of death.

Having thus analyzed the relations, vital and physical, of the chain or tripod

of life, the heart, the lungs, and the nervous system, the nature of *asphyxia*, which consists in an interruption to those relations, will be generally intelligible. The etymology of *asphyxia* implies the very converse of the pathological condition to which the name is applied. It means no *pulse*; whereas the condition to which it is applied, consists essentially in no *breath*. It is true, the pulse must soon cease, as you perceive, when there is no breath; but the characteristic of *asphyxia* is, that there is pulse when breathing has ceased. The name is, therefore, obviously improper. With this understanding, however, and using the term under the figure of *lucis à non lucendo*, we inquire what are the causes of *asphyxia*, that is, what will stop the breath? We see in the diagram an answer with regard to the nerves and their centres,—any thing that cuts off communication with, or any thing

which destroys the function of, this system, whether by physical injury to their mechanism, or by poisons acting on their vitality. But, besides, we have the mechanism of respiration,—any thing which stops that, any thing that renders its movements ineffectual, by cutting off the supply of pure air, annihilates the function of respiration, and stops its essential important effect, the arterialization of the blood. Well, now, let us trace the successive phenomena of this stoppage of respiration, how they follow one another. The oxygenation of the blood in the lungs being arrested, this blood necessarily remains venous; and from the mechanism we should expect it to pass on in this venous state to the left cavities of the heart: a little does so pass; but it is only a little; the greater portion is arrested at the lungs, waiting, as it were, for the supply of air, and being refused any onward progress, the accumulation of blood distends the right cavities of the heart, then the venous trunks, and a great portion of the venous and capillary system; the left cavities and arteries being nearly empty. It was supposed, by Goodwyn and Bichat, that the black blood became distributed through the arteries, and acted on the parts through which it passed as a sort of poison, that suspended their functions, and that thus the death which began with the lungs was transferred throughout the brain and other parts of the frame, destroying speedily the heart also. But Dr. David Williams, of Liverpool, first shewed that very little black blood passes to the left side of the heart, but it is somehow arrested in the now motionless lungs. And Dr. Kay found that slowly injecting large quantities of venous blood into the carotid artery of an animal, did not suspend the function of the brain, nor cause the loss of sensibility which attends asphyxia. Dr. Edwards further proved that the irritability of the muscles of cold-blooded animals is preserved longer when only venous blood flows through them, than when they receive no blood at all, which could not be the case if venous blood had a positively noxious quality. Hence it is probable that the sudden failure of animal life in asphyxia is caused by the great want of supply of blood in quantity, rather than by its venous quality, and that this obstruction in the lungs destroys by soon arresting the circulation throughout the body. Hence the latter phenomena of asphyxia, the failure of the senses, sometimes with slight convulsions, resemble those of syncope, in which the heart at first ceasing to act, the circulation is at once stopped, and the functions of the nervous system also fail. Although, however, the defective quan-

tity of the blood may be the chief cause of the failure of the functions in asphyxia, I cannot but consider the venous quality of that which does circulate, or stagnate, as a concurring injurious influence. This blood, deficient in oxygen, and abounding in carbonic acid, produces in the brain the same symptoms that Nysten obtained by injecting carbonic acid into the carotid artery; and whether this venous blood is supplied directly through the arteries, or made to stagnate in the vessels of the head, by an impediment to its progress onwards through the veins to the lungs, all forms of asphyxia seem to agree in this condition—the presence of black blood, and of only black blood, in the brain and other organs.

A question of great interest arises from the view of the pathology of asphyxia, which the experiments just alluded to develop. The venous blood, not finding oxygen in the lungs, will not pass. What is it that stops it? The right side of the heart continues to beat, even after the left side, no longer receiving its accustomed stimulus, has stopped. The obstruction must, then, be in the lungs; and Haller supposed that the absence of the alternate motions of inspiration and expiration, which must assist the passage of the blood onwards through the capillaries, is sufficient to account for the obstruction. But Professor Alison has lately made experiments which throw doubt on this explanation. He found that when an animal is confined in azote until its breathing becomes laborious, and then killed instantaneously by concussion, the right side of the heart and the veins were as much distended with blood as where the respiratory movements had ceased. Here, he maintains, were the mechanical motions of the lungs, described by Haller, kept up to the last, but the pulmonary obstruction nevertheless existed. Dr. Alison views this obstruction as one of many other phenomena, which seem to prove that the motion of the blood in the capillaries is independent of any contractions or movements in the vessels themselves, or in any of the living solids; that it is caused in great measure by certain vital attractions and repulsions subsisting between the particles of blood and their containing vessels; and that these vital attractions and repulsions are greatly modified by the chemical changes which the blood may undergo in the various organs. In the lungs, the absorption of oxygen promotes through these powers the passage of blood through the capillaries. When oxygen is not present, this power of capillary circulation ceases, and the blood necessarily stagnates. A single breath is, however, enough to set it in motion; and by artificial respiration the

circulation of the blood may be restored after the heart has ceased to act, and when it (the heart) is re-excited by the oxygenated blood reaching it, propagated by these other powers. The correctness of this explanation is involved in the question as to the existence of these powers of vital attraction and repulsion, which is far too extensive for us to enter into here. The view that there are *physical properties peculiar to living structure, vital attraction and repulsion*, as we know there are *peculiar chemical properties, vital affinities*, is quite philosophical in principle; and the number of facts which Haller, and many of his countrymen since his day, have adduced in support of this view, are highly deserving of your attention.

But I confess that I wait for further arguments before I can be quite convinced that this view is absolutely necessary to explain the phenomena of asphyxia. 1st. I do not think that Dr. A.'s experiments are altogether conclusive against the explanation of Haller—that the obstruction of the blood in the lungs is caused by a stoppage of the *natural motions of respiration*. Dr. A. substituted azote for air, and supposed that the mechanical motions of respiration of this would be the same as of air; but from what I have before said, it is probable that air, deficient in oxygen, cannot be so freely respired as common air. Air that is kept until much deteriorated in the lungs, causes a forced expiration; and the reception of the same air again must very promptly excite the same action, until oxygen is supplied; so that the respiration of azote must consist in a preponderance of expiratory over inspiratory efforts, which would tend to retard the passage of blood through the pulmonary vessels, instead of promoting it, as the regular succession of equal in and out breathing does. I do not, however, suppose that this is more than one of the causes which obstruct the progress of blood through the lungs. But, 2dly, there is a contractile power in the blood-vessels which is capable of obstructing, although it cannot promote, the motion of the blood in them. The capillaries themselves do not seem to possess any power of this kind, but the larger vessels (both arteries and veins) have it, and are seen to show it on the application of an unusual stimulus. Now there seems to me nothing unreasonable in the supposition that venous blood is such a stimulus to the small branches of the pulmonary veins, which, being adapted to carry only arterial blood, may thus refuse a free passage to unarterial blood. These considerations will, I believe, go some way in explaining the impeded pulmonary circulation in asphyxia. The passage of blood is not wholly arrested,

but it is impeded enough to cause great distension of the right ventricle; and this distension, as we shall hereafter find, impairs the power of its propulsive action, by keeping open the tricuspid valves enough to cause regurgitation and venous pulse. This venous pulse doubtless answers the salutary purpose of giving a certain motion to the blood stagnating in the veins, which might otherwise coagulate; but it must add to the difficulties against the onward progress of the blood. The left ventricle receiving so little blood, and that not adapted to excite it to its usual activity, and sending so little of the same fluid through the coronary arteries to revive its substance, soon ceases to act; the arterial circulation also ceasing, those parts die which depend on its support, the nervous system dies, the muscles die, and at length the right side of the heart, failing to receive its pabulum through the coronary arteries, dies; and last of all, no longer receiving the vivifying operation of the functions and of motion, the blood coagulates, and dies also.

There is a condition illustrative of the relations of circulation and respiration, which is worthy of attention, as it presents us with a sort of separation of these functions—*hybernation*. When hibernating animals are exposed to a certain degree of cold, instead of exhibiting that power of reaction, of increased activity of respiration and secretion, which enables other animals to generate more heat, and thus to preserve for a time their temperature, they become torpid, gradually lose their temperature, the respiration becomes more and more rare, and at length ceases; and the circulation becomes very slow and very languid. In these animals, cold suspends entirely the animal functions, and greatly reduces the organic, but does not destroy the irritability of the heart, which, continuing to beat, circulates slowly a little venous blood; and this little, which would be wholly insufficient to support the functions when warmth develops them into activity, sustains them in the degree of vitality to which cold has reduced them. Warmth reapplied is the most effectual key to the locked-up properties of life: as the animal becomes warm, its sensibility returns; it feels the want of breath, muscles obey the call, respiration begins, circulation is quickened, secretions are excited, the self-warming power is regained, and the animal is raised, in the course of half an hour, from a state of animation below that of a cold reptile, a condition more like vegetation, to the vivacity and activity of a warm-blooded mammal.

When a hibernating animal is in its most perfect state of torpor, there is apparently no respiration, and the blood

which circulates is only venous. Now as by our diagram we have represented respiration to be the chief link by which circulation depends on the nervous system, this link here no longer existing, we should expect that the dependence which it maintains will be in a measure suspended. Accordingly, Dr. M. Hall found that the circulation of an animal in this state went on for nine hours after the gradual but complete destruction of the brain and spinal cord. Observe, however, that even in this state the nervous system could still influence the circulation; for a violent injury, such as crushing the brain, would arrest the circulation by a positively noxious influence, just as would happen from crushing a limb. So also sensibility is not entirely destroyed, but becomes of a latent and conservative kind, and is capable of being excited and developed into greater activity by strong impressions, or those of a destructive tendency. Thus even an intense cold, such as that of zero, will be felt by a hibernating animal; the sensation will excite the dormant functions, and the animal will awake from the intensity of the same agent that brought him to this state of torpor. The effect of gradual cold seems to be to lower the function of the nervous system in such a way that the lungs and other parts do not feel the want of arterial blood, but in their degraded state to be content with merely venous blood. The effect of sudden intense cold is different, but it illustrates the same point. A warm-blooded animal, suddenly exposed to intense cold, as by being immersed in ice-cold water, is brought into such a condition that the arterial character of the blood is not needed, and the veins return it to the heart in its flacid state; those functions which need arterial blood are paralyzed, and the chemical change from arterial to venous, itself also partly dependent on temperature, is therefore suspended. The paralyzing effect here, however, extends to the heart, which, although receiving arterial blood, cannot obey its stimulus.

The diminution of animal functions which hibernating animals present in the highest degree, is to a certain extent exhibited in most other animals. Thus on a severe winter's day, we see crows and other birds perched still and almost inanimate on the trees; the hunger which they must feel not impelling them to exertion. Even domestic poultry prefer to roost half their day, without food, to the exertion of wandering as they are wont to do in search of it. Nay, the longer sleep which the protracted absence of light in the winter brings on animals, is wisely intended for the same purpose as hibernation—to lower those functions the activity of which would

cause acute suffering at this intense season, and for the maintenance of which there is no longer an external supply. Man, and the animals which he domesticates with him in his artificial state, exhibit the least of this natural adaptation to seasons: for this he substitutes artificial protections and seasons; and thus keeping the functions in their condition of full activity, he incurs, on any accidental neglect of his artificial means, risks from sudden transitions or exposure, from which other animals are comparatively free.

ON THE HUMAN VOICE.

BY PROFESSOR MÜLLER.

[Concluded from page 43.]

IN the cut-out larynx two completely different sets of notes may be produced, when the vocal ligaments have a very slight degree of tension; notes, generally deeper, which have the most exact resemblance to the chest-notes; and others, generally higher, and the highest, which are in sound just like those of the falsetto. These notes may be produced with the same degree of tension; sometimes the chest-notes are given out, and sometimes, with the same tension, the falsetto. In a certain tension of the ligaments the notes have always the sound of the falsetto, whether one blows weakly or strongly. In greater relaxation of the ligaments those produced are the chest-notes, whether one blows weakly or strongly. In very slight tension it depends on the force of the blowing whether chest or falsetto notes are produced, the former being most easily produced by very gentle blowing. For these experiments, which succeed far best with male larynges, the plan last-mentioned must be followed, *i. e.* the arytenoid cartilages and whole larynx must be fixed vertically, the glottis closed posteriorly. They seem to prove that the chest and falsetto notes do not merely depend for their production on particular degrees of tension, as Liscovius supposed, since they may be both sometimes obtained with the same degree of tension; and the chest notes vary not according to the narrowness of the glottis, but according to the greater or less degree of relaxation of the ligaments.

If the vocal ligaments have so slight a tension, or so slight a degree of relaxation, that either chest notes or falsetto notes may be produced by the same means, it is evident that the falsetto notes are not at all of the same class as the flageolet notes (harmonics) on strings, which are pro-

duced by the vibrations of aliquot parts of the length of the string, for the vocal ligaments may be clearly seen to vibrate in their whole length. The essential difference of the two sets of notes consists in that, in the falsetto, the thin edges only of the vocal ligaments vibrate, while in the chest notes, the whole ligaments vibrate freely, and with great excursions. In accordance with this, it is observable that in the production of the falsetto notes, the edges of the ligaments only vibrating, the aperture of the glottis may be clearly seen between them; while, in the chest notes, the excursions are so great, that the glimmer of the vibrations of both ligaments is mixed; and not only they, but the limiting membrane below the lower vocal ligaments, which is covered by the lower part of the thyro-arytenoid muscle, enters into free vibrations.

The chest notes become deeper the more the thyroid cartilage is approximated to the arytenoid; but at last, on great relaxation of the ligaments, notes cease to be produced. If the thyroid cartilage, on the other hand, be drawn forward, the deep bass notes of about one octave may be produced in a good male larynx; but after this the notes pass into a falsetto sound, which is alone generally produced after a certain tension of the ligaments. There are two means, however, by which other and higher chest notes may be produced, viz. either by increasing the force of blowing, by which they may be raised to a fifth, though then they have generally a very shrill harsh sound; or by approximating the sides of the walls of the larynx immediately below the lower vocal ligaments, by a pair of flat instruments, as the handles of scalpels, pressed on the exterior of the exposed elastic membrane which is found at this part, lying upon and within a tolerably thick muscular layer, the lower part of the thyro-arytenoideus. This narrowing of the part of the larynx immediately below the vocal ligaments would seem to be the office of this portion of the muscle, which is also probably of further importance in the parts of it which cover the sides of the vocal ligaments and the ventricle, to which it may act as a damper when they are vibrating with the ligaments, and so produce an elevation of the tone. And again, another office of this thyro-arytenoid muscle will be to alter the vocal ligaments, by the influence its contractions will exercise on their outer borders, to which the muscles are firmly attached. When, for instance, they contract, a lax ligament, such as is necessary for the low notes, may become somewhat stiffer, as in the action of the sphincter oris

on the tension of the lips in trumpet playing.

The action of this muscle may also be imitated by pressing on the sides of the thyroid cartilage and chest: notes may thus be obtained as high as generally attained by the male voice. For example, in the greatest relaxation of the vocal ligaments, by approximating the thyroid to the fixed arytenoid cartilages, a larynx gave the chest note *c*; with less relaxation and stronger blowing, it gave *c'*, but this octave was the highest note attainable by this means. But by compressing the vocal ligaments and the parts below them, from the sides, higher chest notes could be obtained, and even up to *c''*, another octave, and up to this the falsetto notes were perfectly avoided.

From these observations, the following explanation of the chest-notes may be given. The ligaments vibrate in their whole breadth, and the membranes and thyro-arytenoid muscles connected with them, vibrate coincidently. The deepest chest tones are produced during great relaxation of the ligaments, by the approximation of the angle of the thyroid cartilage to the arytenoid: in this great relaxation the ligaments are not only quite unstretched, but are, when at rest, even wrinkled and folded; but the air passing through stretches them, and gives them the tension necessary for vibration. By increasing the tension of the ligaments, the chest-notes may be raised one octave. The most easily produced are those at about the middle of this scale of one octave, which are about the pitch of the natural speaking voice, and are obtained when the ligaments are neither stretched nor wrinkled. The chest-tones are raised to their greatest height by the lateral compression of the vocal ligaments, and the narrowing of the inferior passage to the glottis by the thyro-arytenoid muscles, or, as before observed, by more violent blowing. In the chest-tones, too, the tension of the lips of the glottis by the thyro-arytenoid muscles is to be considered.

In the falsetto notes, the inner portion, or merely the edge of the ligaments, vibrates; they depend for their height on the degree of tension of the ligaments.

None of the parts lying above the lower vocal ligaments are necessary for the production of either the chest or falsetto notes.

The notes easily produced on the female larynx are in general higher than those obtained from the male. The vocal ligaments in the female are generally shorter than those of the male; and from this circumstance (with in a slighter degree the

size of the whole larynx and the strength of its walls) may be deduced the different characters of the male and female voices, as well as the differences in each sex—as

the bass and tenor, the alto and soprano. Müller has measured the length of the ligaments in several cases, and the general result is as follows:—

Average length of vocal ligaments in males, at their greatest extension, 23½ millim.

Ditto	ditto	females	ditto	15½	„
Ditto	ditto	males, while at rest		18½	„
Ditto	ditto	females, ditto		12½	„

Hence, in both conditions, the lengths are in the proportion of 3:2.

These measurements are taken from the attachment of the ligament at the angle of the thyroid cartilage to its attachment to the anterior process of the arytenoid, and the small continuation of the ligament which goes off somewhat further backwards towards the anterior edge of the arytenoid cartilage, is included. The extension in the first measurements is made by drawing the thyroid cartilage forward, while the arytenoid are fixed.

By increasing the strength of the current of air during the same degree of tension of the ligaments, the original note may be raised through a series of half-notes to its 5th, or even higher. Thus if it commence at *g*, which is produced during the weakest blowing, it will, by increasing the violence of the current, go through *g* sharp, *a*, *a* sharp, *b*, *c*, *c* sharp. In this respect the human larynx agrees with the artificial ones made with the moist elastic coat of an artery; but the same effect cannot be produced by the artificial caoutchouc larynges. Hence it seems that there are two distinct modes by which, in the human larynx, the same note may be produced, viz. either by a certain degree of tension of the ligaments proper to it, or by an increased current of air, when the ligaments have the degree of tension proper to another note less than an octave below it. But the character of the note is very different in the two cases; in the former it is full and round, in the latter harsh and squeaking.

The alteration of the length of the tube below and above the ligaments produces very little alteration in the notes,—in no case more than a single note, and generally not more than half a note; yet in the artificial larynges, made either with laminae of caoutchouc or of arterial membrane, the difference is generally considerable, probably from the different nature of the walls of the tubes above and below, which, in the human larynx, are only in certain cases fitted for vibrations, and the greater extent to which the artificial laminae may vibrate. The only influence that the varying length of these tubes would seem to have, is that which may be observed in living persons, viz. that the

elongation of the upper tube by the descent of the larynx, renders the production of the low notes more easy, and that its shortening by the ascent of the larynx facilitates the production of the high notes.

The partly membranous nature of the trachea does not seem to have any influence in modifying the note, which is the same when it is used as when a modern wind-pipe is employed; and the double termination of the upper tube in the mouth and nose seems to be of equally small importance in altering the height of the note, though it somewhat alters its expression by its resonance.

The covering of the glottis by the descent of the epiglottis lowers the note somewhat, and at the same time makes it somewhat duller, otherwise it appears to be of no importance in the modification of the notes; for Müller's experiments do not confirm the ideas of Grenie, Biot, and Magendie, that it serves to raise the note when it is lowered over the glottis, while the current of air is made stronger.

The arches of the palate are narrowed, and the uvula is shortened in the higher chest notes, as well as in the falsetto; and in the same high notes the isthmus faucium is narrowed, whether for chest notes or falsetto. And in either case the arches of the palate may be touched with the finger without the note being altered.

A narrowing of the parts immediately above the local ligaments has no material influence on the note produced, and the only use of the Morgagnian ventricle is probably that of leaving the ligaments free to vibrate, just as, according to the comparison of Malgaigne, the hollow in the mouth-piece of a trumpet permits the free vibrations of the lips.

We pass over the admirable examination of the opinions of other authors which follows the detail of these experiments, which are too convincing to leave any doubt of the correctness of Müller's general conclusion, that the larynx may be compared to a musical apparatus in which the notes are produced by the vibrations of two membranous tongues; but to any who are desirous of being acquainted with the literature and history of the subject, this section presents

itself nearly all that can be required, and gives sufficient references to sources for still further information. We pass on to the section on *Singing*.

He observes, that there are three kinds of sequence in which the notes of the human voice may follow each other. The first is the monotonous, as in common speaking, where the principal differences are produced by the articulation in the mouth, and the notes are only made occasionally higher or lower for the sake of accent and emphasis. The second kind is that where the notes rise or fall in a successive passage from one to another without appreciable intervals, as in the howling and whining both of men and animals. It is imitated by the wind, by a string, which, having been put into vibrations, is gradually drawn tighter while sounding,—or by the increasing violence of the current of air blown into some pipes, or on membranous tongues, or on the vocal ligaments. The third kind is the musical, in which each sound has its proper number of vibrations, and the following notes have certain definite proportions of their number of

vibrations, or are marked by definite intervals according to the musical system of notes. It has rhythm also in common with poetry.

1st. *Of the Compass of the Voice*.—The compass of the voice is from 1 to 2 or 3 octaves,—that of singers is generally from 2 to 3. But the voices of males and females begin and end at different parts of the scale. Taking as *C* the great *C* of the 8-feet open or 4-feet covered organ pipe, the male voice would begin at *E* or *A*, or *c*, and would go up to *a* or further, or to *f'*, or to *c''*. The female voice is as deep as this only in viragos. The voices of women, children, and eunuchs, begin between *f* and *c'*, and reach to *f''*, or *a''*, or *c'''*, or at the very highest to *f'''*. Thus the lowest note of the female voice is about an octave higher than the lowest of the male, and her highest about an octave above his highest: so that the whole compass of the human voice is about 4 octaves, viz. from *E* to *e'''*, taking as *C* the 8-feet open *C* organ pipe, and as *c'''* the 6-inch open organ pipe. This is better explicable by the following diagram:—

The elder Fischer could sing as low as *F*; the youngest of the sisters, Sessi, had a compass of 3 octaves and 3 notes, viz. from *c* to *f'''*; Zetter had one of 3 octaves, and Catalani of 3½.

But the different range of the voice is not the only thing that distinguishes the male from the female, or, in the same sex, the alto from the soprano, or the bass from the tenor: there is a peculiarity in the tone of each,—such, that although their compass might be the same, or though both singing the same note, the one might be distinguished from the other; and on the same differences, in a slighter degree, depend the less evidently distinguished kinds of voice, called barytone, mezzo-soprano, counter-tenor, contralto, &c.

The difference between the pitch of the male and female voices depends principally, as before observed, on the different lengths of the vocal ligaments, which have the proportion of 3 to 2. The difference in their peculiar tone depends on the form and quality of the resounding walls, which in the male are much larger, and form a greater angle at the anterior part of the thyroid cartilage. The difference of tone between the tenor and bass, and the alto

and soprano, depends probably on some peculiarities, at present undiscovered, of the ligaments and resounding walls,—as in various instruments peculiarities of tone are produced by different materials, as metallic or catgut strings—metallic, wooden, or membranous tongues—or metallic, wooden, or paper resounding walls; for these instruments, though set at the same note, have each a different and peculiar tone or timbre.

Boys' voices are altos or sopranos, like women's; and after the further development of the larynx at puberty (before which it presented the same form as that of females) become basses or tenors. During the development of the larynx, the voice is peculiarly harsh and uncertain, and hence at this period is generally said to be *breaking*. In eunuchs deprived of virility before puberty, the voice is not altered, and they retain the female tone throughout life.

Most persons, and especially males, have the power of modifying their voice according to a double set of notes, viz. that of the chest notes, and that of the falsetto. The chest notes are fuller and rounder, and the lowest notes of the voice are heard only in them; the falsetto are more shrill,

and contain the highest notes of the voice, while the middle notes can be produced in either scale. The two scales are therefore not exactly limited by one another, but in the middle notes of the voice run into each other. A tenor, for instance, begins to pass into falsetto at *a'*, while the notes below this can be sung with either kind of voice: the bass, of course, begins falsetto earlier. In women there is seldom a sufficiently evident difference between the chest and falsetto notes.

The peculiar slight differences distinguishing the voice of each person also probably depend on some slight peculiarity in the form of the air-passages and membranes and their resonance; and hence, by alterations of the form of their own organ, many persons can imitate the voices of the most different individuals. The nasal voice or twang may be produced in two ways: with the nostrils closed externally, both it and the natural voice may be produced; the latter when the arches of the palate are open, the former when they are approximated,—in which case the larynx is much more raised than when the same note is given in the natural voice. In this case the nasal cavity becomes a separate resounding chamber. Or secondly, the nasal voice may be produced with both nose and mouth open externally, by raising the larynx, approximating the arches of the palate, and moving the back of the tongue towards the palate, so as even to make them touch; the air then goes only through the narrowed palatine arches, and receives the resonance of the nasal cavities with that of the cavity of the mouth.

The voice of old people loses in tone, in certainty, and in compass; the first by the ossification of the cartilages, and the changes in the condition of the ligaments; the second by the partial removal of the command of the nerves over the muscles, from which here, as in the other parts of the body, a trembling motion is produced; while, from both these causes, the voice becomes weaker, and shaking.

The power of the voice depends on the capacity for vibrations of the vocal ligaments, and partly on the fitness for resonance of the membranes and cartilages of the larynx, thoracic walls, lungs, oral and nasal cavities, and the cavities adjacent to the nose. Hence much of it is lost in inflammation of those parts producing a copious secretion of mucus, or other changes. The variations in loudness with which the same note is sung by the same voice, cannot depend merely on the varied energy with which the air is forced through the glottis, because, as was before shewn, a mere increased force of the current of air, while the vocal ligaments retain the

same length, has the effect of raising the note even to its fifth. It is probable that this elevation of the note which would be produced merely by an increased force of the air, is compensated by a corresponding relaxation of the ligaments; so that, for instance, in proceeding from a piano expression to a forte, the ligaments are relaxed just in proportion as the force of the current of air is increased, and the opposite in proceeding from forte to piano. Another means of compensation may be by the narrowing or widening of the portion of the air-passages immediately below the vocal ligaments. It has been shewn that an elevation of the note is produced by the contraction of this part, and hence it may be, that as the current of air is increased in force, this part of the tube is widened, and *vice versa*.

Man, like a singing bird, learns unconsciously the internal alterations of the larynx, and the muscular actions necessary for each note. Accidentally uttered notes, and the muscular actions producing them, become associated, and in time are made to follow each other in order when a melody is to be imitated. In methodical learning of singing, a knowledge of the signs indicating the notes is added to the association of the notes heard, and the muscular motions necessary to produce them. For all this, and to give to each note a harmonious expression, a good ear is necessary, for without it there may be a voice of extensive compass and great beauty, but there can be no good application of it, or singing.

One remark must be made on the beautiful arrangement of the apparatus of the human voice. No musical instrument can be compared with it, for even the most full organs and pianos are in some respects incomplete. Some of these instruments are incapable of passing from piano to forte, as in the labial pipes; others cannot rest long on the same note, as all those which are sounded by striking. The organ possesses two scales, from the labial and the tongue-pipes, and is in this respect comparable with the human voice, with its chest and falsetto notes; but none of these instruments unites all advantages like the human vocal organ. It belongs to the class of those that have tongues; and these, when united with a system of compensating pipes, are (next to the violin) the most complete of all. Yet again, the vocal organ has this perfection, that from one tongue-pipe the compass of the whole gamut, and all the required variations, may be produced, while in the most complete artificial apparatus each note must have its own pipe. An artificial imitation of this organ would be in some measure attained, by the arrangement of

a tongue-pipe with an apparatus easily manipulated to produce the required degrees of tension of the elastic bands; but the tone of such an instrument, for which only dry elastic bands could be used, would not be able to imitate the soft full tone of the moist animal elastic tissue, and there always would be a great difficulty in manipulating it.

DISSECTION OF AN OLD DISLOCATION OF THE THUMB,

WITH REMARKS AND EXPERIMENTS,

By J. ADAIR LAWRIE,

Professor of Surgery, Andersonian University,
Glasgow; Senior Surgeon, Glasgow Royal Infirmary.

I AM indebted to Dr. Hunter, Andersonian Professor of Anatomy, for permission to examine and make public the following case:—A female subject was brought into Dr. Hunter's dissecting rooms during the course of last winter, with an unreduced dislocation of the phalanx of the right thumb, on the back part of the metacarpal bone. It was ascertained on inquiry, that the dislocation had existed for three years, and that several unsuccessful attempts had been made to reduce it. The motions had been partially restored and performed without pain. Previous to dissection, the phalanx was seen to be thrown back, with an anterior and posterior prominence. The thumb shortened, the second phalanx not bent on the first, and the articulation between them capable of free flexion and extension. There being no swelling, the nature of the accident was obvious.

Dissection.—*Bones*: the end of the phalanx was thrown on the back and inner part of the metacarpal bone, to the distance of at least an inch. The circumstance of the phalanx being placed on the inner side of the back part of the metacarpal bone is worthy of notice, as I believe that it is almost uniformly so situated in this dislocation. The end of the metacarpal bone projected forwards to a distance corresponding with the displacement backwards, free from muscle or ligament.

Ligaments.—The anterior ligament torn from metacarpal bone; the posterior pressed back, but apparently nearly entire. The anterior portion of external lateral torn; the posterior por-

tion stretched, thrown back and across the metacarpal bone; the internal entire. New ligamentous connexions had formed between the displaced bones.

Muscles.—Extensors thrown back, and somewhat stretched over the end of the phalanx; of these, however, I cannot speak with certainty, as they were cut before I examined the preparation minutely. Abductor thrown back, and a little stretched. Opponens a little changed. Flexor brevis: on this muscle, and the flexor longus, the alteration of position was most remarkable. Dr. Hunter thought that the brevis was not torn, but that the end of the metacarpal bone had passed between its two portions, one of which was on each side of it, grasping it firmly. Further examination induces me to think that the greater part of the outer head was torn, the end of the metacarpal bone having passed through its fibres, and that the inner head was uninjured, having slipped to the inner side of the metacarpal bone. The tendon of the flexor longus lay on the inner side of the metacarpal bone, along with the inner head of the brevis, pressing on the abductor, and pushing it back, which last muscle, with this exception, was unchanged.

Nerves.—The first, or external digital nerve, is thrown to the inside of the metacarpal bone, and lies imbedded between the phalanx and metacarpal bone, at the points where the former rests on the latter.

Sesamoid bones were not connected with the metacarpal bone. It was found that it would injure the preparation if the dissections were carried so far as to ascertain if they were placed between the metacarpal and the phalanx, in which situation I have, however, no doubt that they are.

Although there are several points in the above dissection which were new to me, they had rather the effect of unsettling my previous opinion as to the cause of difficulty in reducing this dislocation, than of satisfying me as to what that cause really is. In the hope of farther elucidating this point, I proceeded to make experiments on the dead body. To detail all these experiments and dissections (and I have made a great many), in the order in which they were made, would be tedious and unnecessary. I prefer arranging them into three classes, according to the

amount of dislocation produced, and giving one dissection as an example of each class. The experiments consisted in dislocating the articulations, by grasping the phalanges of the thumb and bending them powerfully backwards; and the dissections, in dissecting the parts, and removing one layer of muscular fibres and of ligaments after another, so as to ascertain the true cause of the difficulty of reduction.

I. Partial dislocation.—The external characters are—anterior and posterior prominences slight; the posterior projects directly backwards. Phalangeal articulation bent like the dog-head of a gun, and cannot be extended; disfigurement considerable.

Dissection.—No muscular fibres torn; abductor and both heads of flexor brevis somewhat stretched and thrown a little back; tendon of flexor longus considerably stretched, but not displaced, retaining its natural position on the forepart of the articulation between the two heads of the brevis.

Ligaments.—Anterior partially torn; posterior entire, stretched; external lateral has a few of its anterior filaments torn, its posterior stretched; internal lateral entire, a little thrown back. Articular extremities of bones partially displaced; that of phalanx backwards, and very slightly inwards. Reduction was easily effected; all that was necessary was to extend the articulation between the phalanges; the flexor longus tendon, when brought into a straight line, drew the bones into their place.

REMARKS.—I have never seen this dislocation on the living subject. It probably seldom requires surgical treatment, being reduced by the action of the flexor longus or by pressure made by the patient over the articulation. The muscles are too little displaced to oppose much resistance to the reduction.

II. Complete dislocation.—External characters: anterior and posterior prominences well marked; the latter a little to inside. Articulation between phalanges bent, but can easily be extended.

Dissection.—Abductor and adductor nearly as in last experiment. Inner half of external head of flexor brevis torn by the end of the metacarpal bone; remaining part lies on the outside of the

bone, and thrown back. Internal head lies to the inside of the bone, and somewhat backwards. Tendon of flexor longus thrown from off forepart of articulation to inside of metacarpal bone, and carried considerably backwards, pressing on inner head of brevis and adductor; that part of its sheath connecting it with the articulation, and the end of the metacarpal bone, torn; that connecting it with phalanges entire. Anterior ligament torn, excepting at inner side; posterior entire, stretched; internal lateral entire; anterior part of external lateral slightly torn; posterior part stretched, thrown back, and a little across end of metacarpal bone. Displacement of phalanx backwards does not exceed half an inch. Sesamoid bones remain attached to phalanx. Reduction on dead subject easily effected.

REMARKS.—I should not anticipate great difficulty in reducing this dislocation on the living. The causes opposing reduction I conceive to be the following:—

1st. *Muscular contractions.*—The muscles least affected and most easily overcome, are the extensors, abductor, and adductor. The flexor brevis and longus are less easily dealt with; we have seen the metacarpal bone driven through the external head of the brevis, and so situated as to be firmly grasped between its remaining fibres and the internal head, the tendon of the longus on the inside of the articulation dragging the phalanges inwards, and locking them in contact with the metacarpal bone. These, though rather formidable obstacles, are within the control of bleeding, antimonials, and the pulleys.

2d. *Ligaments.*—My experiments lead me to conclude that the lateral ligaments have been reckoned of greatly too much importance in this dislocation. If they are the causes of difficulty, the reduction ought to be nearly as difficult on the dead as on the living, which in this degree of dislocation is by no means the case. It is quite a mistake to suppose that the end of the metacarpal bone is grasped by the lateral ligaments, and cannot escape. The internal lateral ligament is little, if at all, implicated in the matter; the external may result in this way. The phalanx being thrown inwards, the external lateral ligament is dragged with it, and thrown a little across the back of the metacarpal bone,

and in attempts to reduce the dislocation, catches on the prominence, on the outer and back part of the same bone. If the phalanx is pulled forwards and bent across the palm of the hand, the resistance will probably be considerable, but never such as to require or justify the operation of cutting the ligament. To overcome the difficulty, use the pulleys, press the bones asunder by pushing the metacarpal bone towards the palm, the phalanx towards the dorsum, extend the thumb towards the points of the fingers, not across the palm; next press the metacarpal bone backwards and inwards, the phalanx forwards and outwards; lastly, smartly bend the joint.

3d. The third cause of resistance is the locking of the prominences on the back part of the metacarpal bone, and the fore part of the phalanx. The manipulations recommended ought to overcome this difficulty.

III. This dislocation is also complete, and differs from the last in the following respects:—The displacement is greater, amounting at least to an inch. The end of the metacarpal bone is driven completely through the inner fibres of the external head of the flexor brevis. The anterior ligament is completely torn from the metacarpal bone, and remains attached to the phalanx and sesamoid bones, in such a manner that the torn ligament and sesamoid bones are carried backwards by the phalanx, and placed between it and the metacarpal bone. This state of parts is aggravated and rendered permanent by the contraction of the muscles attached to the sesamoid bones and anterior ligament, which muscles, together with the tendon of the long flexor, only differ from their position as described in last section, in being carried farther back. The result is, that the opening in the ligaments by which the metacarpal bone escaped, is thrown back nearly half an inch, and the remains of that ligament and sesamoid bones form a partition between the displaced ends of the bones, which form a mechanical obstacle to the reduction of the dislocation, in some instances I fear insurmountable. This, I am satisfied, is the true cause of the difficulty experienced in replacing the bones in some cases, and of total failure in others. The position of the digital nerve, in Dr. Hunter's preparation,

proves that besides the sesamoid bones and ligament, whatever parts are more firmly connected with the phalanx than with the metacarpal bone, will follow the former backwards, and be wedged between it and the latter. It must further be kept in mind, that, in addition to this mechanical obstacle, we have all the causes of resistance mentioned in the last section.

How are these difficulties to be overcome? I fear, as already hinted, that in many cases the reduction is impossible, without the infliction of an unwarrantable extent of injury on the thumb. I have not yet, in practice, met with an "impossible" case; but whenever the displacement is great,—and I believe the amount of mechanical obstruction will generally correspond with the extent of displacement,—I would recommend the following:—Take a door-key, the open part of the handle of which will rather exceed the length of the first phalanx; put the thumb through it, apply the pulleys, give tartar emetic, and bleed to faintness; extend the pulleys (in the direction recommended in last section) as far as can be safely done; employ the manipulations already described, assisting the flexion with the key, so used that the curve which lies on the dorsum will press on the nail end of the first phalanx, and the opposite curve on the end of the metacarpal bone. This failing, reverse the key, carry the under curve towards the point of the thumb, place the posterior on the displaced end of the phalanx, and throw the parts into forced extension, relaxing at the same moment the pulleys.

I disapprove of cutting; but if a knife is used, employ one which is narrow but strong; pass it into the joint and between the bones, in such a manner as (if possible) to disengage the anterior ligament and sesamoid bones from their unnatural position. This attempt should be made while the pulleys are in operation. As the external lateral ligament is not the cause of the mechanical obstruction, it is cruel to cut it: moreover, it is useless. I have cut it on the dead subject, and failed to replace the bones. Indeed, I believe that those cases in which the external lateral ligament is most extensively torn, are the most difficult to reduce, because in them the displacement is greatest; and in proportion to the extent of displace-

ment the mechanical obstacle is increased.

Glasgow, August 1837.

P.S.—Since writing the above I have had the great pleasure of being introduced to Sir Astley Cooper, during his short visit to Glasgow. I took the opportunity of asking him what he considered the cause of the difficulty of reducing the dislocation. He at once replied—"The sesamoid bones." I asked if he had verified this by dissection or experiments. To which Sir Astley answered—"In the great toe, but not in the thumb; but I am satisfied that the causes are the same in both." I then mentioned to Sir Astley what I had done on this subject; and I have great satisfaction in being allowed to give his very high authority in confirmation of the opinions given in this paper.

Sept. 26, 1837.

NITRATE OF SILVER IN SOME CUTANEOUS DISEASES.

To the Editor of the Medical Gazette.

SIR,

SINCE the publication of Mr. Higginbottom's Essay on the Use of Nitrate of Silver, cases have appeared, from time to time, in the MEDICAL GAZETTE, and other periodicals, bearing testimony to its value, applied in the manner or to the class of affections in which it is recommended by him. If the following observations on its local use in certain cutaneous diseases possess sufficient interest to procure their admission into the pages of the GAZETTE, they are at your disposal.—I am, sir,

Yours obediently,

HENRY T. CHAPMAN.

2, Argyll-Street.

Having been engaged, whilst house-surgeon to St. Bartholomew's Hospital in 1830, in testing the efficacy of the nitrate of silver in external inflammations, according to the method employed by Mr. Higginbottom, I was led to extend my experiments from erysipelas and inflammation of the absorbents first to cases of erythema nodosum, and afterwards to squamous affections of the skin. Before I proceed further, it may

not be amiss, perhaps, to remind your readers of Mr. Higginbottom's mode of applying it. After cleansing the skin with soap and water, and drying it, the surface to be submitted to its operation is again moistened, and a solid stick of the lunar caustic is rubbed lightly over it once or twice, according to the delicacy of the skin, and allowed to dry. No dressing is required, and the part must be kept cool. The slight vesication produced after the first twenty-four hours soon subsides, and about the fifth day the black pellicle loosens and peels off.

The following are the results obtained by me. Of erythema nodosum two cases were treated; in one of them the redness and induration disappeared entirely after a single application of the caustic; in the other it was necessary to repeat it once more. My next experiment was made on squamous affections of the skin; lepra, namely, and several varieties of psoriasis*. I possess the details of more than a dozen cases successfully treated by it, and have since employed it with equal success in a great number of instances, of which I have neglected to take notes. I select two of those by me as examples of its action.

Thomas Henshaw applied Oct. 8th, 1829, as an out-patient at St. Bartholomew's Hospital, with an eruption of psoriasis diffusa upon both arms. He has been teased with it about eighteen months. His general health has been always good.

November 23d.—During his attendance up to this time a variety of means have been tried; antimonials, mercurial preparations, and mineral acids, internally; locally, sulphuret of potass, as a lotion, and the diluted nitrated mercurial ointment; all without the slightest effect on the disorder. The worst part of the scaly surface was, therefore, rubbed over with nitrate of silver.

30th.—The cuticle having desquamated from the part acted on, has left the skin in a tolerably healthy state; the situation of several of the worst patches being merely indicated by a little roughness. A fresh portion was treated in the same manner, and Plum-

* Dr. Graves, of Dublin, expresses an opinion unfavourable to the use of the nitrate of silver in psoriasis. See the *Medical and Surgical Journal*, March 1835.

mer's pill directed to be taken in five-grain doses every night.

Dec. 7th.—The second application has been as effectual as the first. No re-appearance of the disease over that part of the skin to which it was first applied. The whole remaining surface treated by the nitrate.

14th.—On examining the arms to-day, a roughness only of the skin, where the disease existed, is to be observed. No fresh scales have made their appearance. The pills to be continued.

Jan. 4th.—Came to show his arms, which are now quite free from eruption.

Mary Ghost, æt. 17, attended first as an out-patient, in August 1829, with *lepra vulgaris* over the arms, legs, and body. It commenced by circular patches on the body, more than twelve months back, and has since extended over the limbs.

The liquor arsenicalis, hydrarg. oxy-murias, pilul. hydrarg., submur. comp., warm baths, and other measures, have been employed up to this time, Dec. 14th, not only without improvement, but without arresting its further progress, and I determined to try the nitrate of silver, as in Henshaw's case.

Jan. 11th.—Applied it to the right arm, and on the 15th to the left.

19th.—Where the cuticle has peeled off, the scales have disappeared, leaving a slight roughness here and there; to these spots it was re-applied.

Feb. 1st.—The arms are perfectly cleared of the eruption. The back, and afterwards the legs, were treated in the same manner.

March 26th.—The *lepra* has wholly disappeared. As a precaution, I made an issue in the arm.

May 24th.—She applied for some aperient pill; no return of the eruption. Health better than it has been for some time.

Neither in the above cases, nor in any others, has the treatment been solely and exclusively local. Alteratives were given, and other general means always adopted preparatory to, and continued during, the employment of the nitrate of silver; but it is fair to attribute the immediate amendment to the local remedy, since the same measures had been persevered in fruitlessly, for many weeks in some instances. In *psoriasis palmaris* I find it necessary to soak the hand in warm water

for some time before the nitrate can act with effect through the horny, ragged, and everted flakes of cuticle. The surface, also, bears rubbing over more freely, and three or more series of applications are required to restore the skin to its natural condition. It is very true that relapses occur sometimes; but the repetition of the process will again remove the disease, and the intervals between its recurrence, when it proves obstinate, are generally considerable.

Besides the squamous disorders above mentioned, I have made trial of the nitrate of silver upon other cutaneous diseases.

In *porrigo*, a strong solution of it is recommended by some practitioners almost as a specific. It was, I believe, a favourite remedy with Mr. Wilkinson, who acquired some celebrity for his treatment of this troublesome malady. I have tried it repeatedly both in solution and in the solid state, but in neither form was any permanent advantage gained by it.

In *sychosis menti* and *eczema*, in both of which disorders, as well as in *herpes zoster*, its efficacy has been rated highly. I have been equally disappointed. In short, as far as my experience of its beneficial effects in diseases of the skin extend, it exerts a decided influence over those of a squamous character alone.

With regard to the management and curative powers of the nitrate of silver in *erysipelas*, inflammation of the absorbents, and other superficial inflammations, I have a few remarks to make.

Erratic *erysipelas* I have sometimes seen confined within the belt of blackened cuticle produced by it; but in severe cases it more frequently steals beyond the margin, and spreads as before. Nor has the strong solution, as recommended by Dr. Elliotson, been more efficacious.

In inflammation of the absorbents arising from punctures during dissection, &c. the nitrate, resorted to early, almost always proves completely successful; but when the case has reached the verge of suppuration, or after that has actually occurred, its operation may be highly injurious. The symptoms become masked, and fluctuation difficult of detection; for, instead of making its way to the nearest surface, the pus appears to shrink (if I may so express myself) from the coating of ni-

trate of silver, and spread to a more remote point in search of a vent; producing, in some instances, serious mischief by its separation of the tissues. The following case will exemplify this:—

—Dunn, a man about 24, was admitted into St. Bartholomew's Hospital in the beginning of April, 1830, with inflammation of the absorbents along the inside of the knee and thigh, proceeding from a cut across the front of the leg, received a few days previously. The nitrate was applied, with speedy relief to the pain and heat, and in four or five days the cuticle peeled off, restoring to the skin its natural appearance. The next day a slight blush was noticed on the inside of the thigh, accompanied by trifling fulness; but the most careful examination failed in discovering fluctuation. The caustic was once more resorted to; but, before the period of the separation of the cuticle had arrived, a general fulness of the inside of the thigh became manifest. A poultice was immediately directed, and on the removal of the black coating, the presence of matter, deeply seated, was distinctly ascertained.

April 6th.—The abscess was opened, and more than half a pint of pus evacuated from a cavity dipping between the rectus and adductor muscles. This space filled, in the course of the succeeding twelve hours, with a coagulum of venous blood, which was renewed as fast as removed, distending the cavity to such a degree that the probe met with no obstruction to its passage near the inside of the neck of the femur, to within a short space of the back of the thigh; and the finger could reach, without difficulty, the soft parts which close the obturator foramen. A bandage and compresses were applied; a discharge of pus, free from blood, was soon established; his health, which had suffered much from sympathetic fever, improved daily, and the cavity gradually filled up and cicatrized. A stiffness of the hip-joint remained for some weeks after his discharge, which finally disappeared altogether.

In a second case treated by the nitrate, one of incipient sympathetic bubo, a considerable accumulation of matter formed insidiously beneath the blackened surface, and pointed behind the adductors, near the buttock.

Such results should teach us, therefore, to be cautious in resorting to this

remedy where suppuration is impending.

It still remains to consider the principle of action of the nitrate of silver, upon which Mr. Higginbottom does not advance an opinion. Its effects under certain circumstances, as that gentleman observes, are clearly something more than those of a mere escharotic. Indeed, destruction of surface can scarcely be said to follow its ordinary application to the mucous membranes of the eye and pharynx. By its stimulant or astringent property, or some peculiar power resident in it, the calibre of the enlarged vessels is reduced, and they appear to recover their tone. It may exercise an influence over the nerves of the part: at any rate, two of the characteristics of inflammation, pain and heat, always yield to it*.

Supposing similar effects to be produced on the capillaries and nerves of the skin, the influence of the nitrate on cutaneous and subcutaneous inflammations will not be difficult to explain; and, reviewing its operation in the foregoing cases, such a supposition appears by no means destitute of foundation. In the successful instances of its employment in inflammation of the absorbents, we are justified in concluding that it directly controls the increased vascularity, &c. of the lymphatic vessel, and subdues the inflammation at once. In the cases where, from its tardy application, or from some other cause, it did not prevent the formation of pus, it appears to have occasioned the burrowing of the matter between the muscles, by checking the operations of the capillaries, and transferring the evacuating process, which would otherwise have been conducted at the dermal side of the abscess, to another part of the sac.

In several cases of small collections of matter about the throat and neck, as soon as obstruction to its external escape has been offered by the presence of the black pellicle, I have observed that the pus has been gradually taken up, and entirely carried off, by the absorbents—a practical point of some value in the treatment of these abscesses in females.

In squamous disorders of the skin, besides the separation of the loaded cuticle, the nitrate appears to correct the diseased action of the capillaries, on

* I have lately heard the term "alterant action" applied to its effects on inflammation of the conjunctiva, by Dr. Kerst, of Utrecht.

which the accumulation depends, and restore a healthy tone to the vessels.

This result, however, can never be expected, while the original source of the disease still exists in the system; and before the local remedy can produce any permanent benefit, constitutional measures must be steadily enforced. Some may exclaim that the cure, in that case, is unjustly ascribed to the nitrate; but is it not highly probable that the diseased product still continues to be formed *habitually*, long after the state of health giving rise to such an excretion has been completely rectified? In these affections, therefore, the nitrate of silver is only to be looked upon as an auxiliary to other remedial means, which must always occupy the foremost place.

NITRATE OF SILVER IN THE GONORRHŒA OF FEMALES.

To the Editor of the Medical Gazette.

SIR,

HAVING observed, in a late number of the MEDICAL GAZETTE, a communication from Dr. James McCune Smith, regarding the use of the solid nitrate of silver in gonorrhœa of females, I have been induced to submit to you the following observations regarding that most valuable remedy, which I have made since 1st July last, whilst officiating as clerk to Dr. Hannay, in the Lock Hospital here.

I have seen the solid nitrate of silver employed in now upwards of forty cases of gonorrhœa, and shall make a few remarks on each of the effects produced in their order.

Pain.—When the caustic-holder is well lubricated with any simple ointment, its surface being free from all irregularities that may tend to injure the walls of the vagina—when no rudeness is used in its application, and, above all, when no ulceration of the parts to which it is applied exists—the pain is very trifling indeed; in many instances none whatever. Often have I seen amazement depicted in the countenances of the by-standers, on witnessing the placid and careless appearance of the patient after the operation. As a proof that the patients themselves think

lightly of the pain, I may say that in not a few instances have I been strongly urged by themselves to apply it a second time, even after they were completely recovered, and generally on the day they received their dismissal. Their reasons for this singular request I could not for a long time obtain, until one, more forward than the rest, told me, “that as one application cured them so quickly, a second would perhaps make them proof against a future attack of the disease.”

In the first cases in which I saw the nitrate employed, the patients evinced symptoms of great fear and seeming pain; these symptoms, however, were found to be equally severe when, instead of the caustic, a common silver catheter was introduced. After considerable investigation made by Dr. Hannay into the origin of this fear, sufficiently obvious reasons were made apparent. An example of these is given in the following report, taken from the journal, page 230.

“M. F. July 4.—Will not submit to treatment from fear. She says Dr. McC. Smith frequently told her of the ‘*terrible roastings*’ that Dr. Hannay would give her when he came on. She is therefore so terrified, that she would rather leave the house than submit to treatment, though told that nitrate of silver was not necessary in her case.”

This terrifying system, according to the testimony of several of the patients, had also been exercised by Dr. S.’s successor in office. It would be needless, on my part, to make any comment on such conduct as this; it of itself speaks volumes.

Irritation.—Many individuals, I am aware, consider pain as a concomitant to irritation, and, I believe, it generally is so; but experience teaches me that it is not always the case. Patients whom I have interrogated every hour, for hours after the application of the nitrate, as to whether they suffered much pain, have generally answered me, “No, not much; not worth the speaking about;” and the like,—yet on the following day displayed some irritation. In one instance, owing to prolapsus vaginae, half of the caustic cylinder (about a drachm) was broken in the vagina. Knowing, however, that no evil consequences followed similar accidents at a previous time, it was allowed to remain.

Next day there was very considerable irritation of the external parts; but even in this case the pain was comparatively slight.

In those cases where the irritation is any way severe, the patient is ordered to inject tepid water, which always allays it in two or three days.

Efficacy in suppressing the discharge.—It is completely established in my mind, from observation, that all cases of uncomplicated gonorrhœa in the female may be cured by the solid nitrate of silver in from *three to ten* days. Strangers visiting the Lock, after witnessing the examination of from 25 to 30 patients, have often asked me, with astonishment, whether we had no case of gonorrhœa at all in the house? The answer generally was—not a single case. It is seldom, indeed, that we have an opportunity of exhibiting a case of gonorrhœa to a stranger, unless it happens that a new patient labouring under it is admitted at the time.

Relapses.—The number of relapses that required a second application of the nitrate, amounts to about eight or ten per cent. There is, however, every reason to believe that the manipulation, in these cases, was improperly done, as since the latter end of July no instance of relapse has yet occurred, I having seemingly, from experience, become more perfect in the mode of its application.

In conclusion, I would remark that Dr. Hannay certainly deserves the highest meed of praise for his introducing a remedy so efficacious, and at the same time so economical: efficacious, from its producing a cure in about as many days as it formerly occupied weeks—and economical, from the short space of time the patients are kept in the hospital, independent of the small cost of the remedy. And I can now confidently assert, from fifty cases in my own experience, that it is devoid of the shadow of an evil.

You will confer on me a particular favour by giving the above observations a place in an early number of your most valuable Gazette.

I am, sir,

Your most obedient servant,
JAMES CROSS.

Glasgow,
30th September, 1837.

DR. GRAVES ON THE TREATMENT OF CHOLERA.

To the Editor of the Medical Gazette.

SIR,

As spasmodic cholera seems likely to fix itself permanently in Europe, and has lost nothing of its original malignity, every practitioner is imperatively called on to communicate whatever he thinks may prove serviceable in its treatment. This disease prevailed epidemically to a fearful extent in Dublin in 1832 and 1834. In the former year my practice among cholera patients was very extensive, but by no means successful. In 1834, about the latter end of July, when the disease was raging most violently among the middling and better ranks of society, and at a time when I had very frequent opportunities of treating it, too often had I to regret the inefficacy of the means employed, and though aided by the advice of the most eminent members of the profession in Dublin, too often had I to witness the loss of cases, not apparently very dangerous when they began, and which seemed to leave full time for the employment of remedies, if such were known. Under these circumstances I lost an intimate and highly esteemed friend, Surgeon Ryan, of Camden-street. He was a young man, of vigorous health, and the late Mr. McNamara and I saw him many hours before any symptoms of collapse had set in; calomel and opium, blisters, frictions, sinapisms, stimulants, and all the most approved medicines, were diligently tried, but in vain; and from that moment I resolved to lay aside the mercurial treatment, which had so very often disappointed my expectations, although pushed to the greatest extent, and applied with the greatest activity and perseverance. During the preceding months of May and June, I had treated several cases of diarrhœa in fever with large doses of the acetate of lead, according to Dr. Bardsley's plan, and I had had frequent opportunities of admiring the efficacy of this salt in checking profuse alvine discharges. Just as Mr. Ryan died, and while my mind was filled with regret at our failure in his case, I was called by Dr. Percival Hunt to see a lady in Nassau-street, labouring under dysentery; I advised

the free use of acetate of lead, and with marked success. Immediately after, I saw a case of cholera still in the stage of premonitory diarrhœa, or rather just passing from the bowel complaint into the fully formed disease. I tried the acetate of lead boldly, and with the happiest success. Thus encouraged, I applied this new method of treatment in every case to which I was called, and I was employed both night and day in visiting cholera patients, and every hour gave me additional proofs of the efficacy of the remedy. My formula was as follows:—

R Acetatis Plumbi ℞j.; Opii, gr. j. m.
fiat secundum artem massa, in pilul.
xii. dividenda.

The premonitory diarrhœa has almost invariably stopped by taking one of these pills, at first every hour, and as the stools became less frequent, every third or sixth hour, according to circumstances. When the vomiting, spasms, and the state of collapse had begun, it was necessary to give a pill every quarter of an hour: after a couple of hours the effect of the pills became perceptible, in a diminution of the serious evacuations upwards and downwards; then the pills were given only every hour, and as the symptoms yielded they were given less and less frequently, and could in general be laid aside altogether before twenty-four hours. In some it was found necessary to give the acetate of lead in solution, combined with a little vinegar and minute doses of acetate of morphia. Minute doses of opium were useful; any thing of large doses hurtful. Mr. Parr, the able and respected apothecary of the Meath Hospital, was saved by acetate of lead, after the usual astringents, combined with large doses of opium, had been fully tried. He was found by me to be sensibly under the narcotic influence of opium, but the peculiar symptoms of cholera had not been thereby checked. Many took more than forty grains of the acetate of lead in twenty-four hours; it usually darkened, or even blackened, the alvine discharges, before they ceased altogether. Were I to enumerate all the cases of violent cholera that yielded to this treatment, I would be led into a tedious but not an uninteresting detail; I shall, therefore, merely refer to some of the most malignant cases, where the recovery of

the patient was undoubtedly owing to the bold exhibition of acetate of lead, and where the success of this practice was acknowledged by witnesses the most unexceptionable and competent.

Mr. Peile, Deputy Inspector General of Hospitals, and Staff-Surgeon Coleclough, will not readily forget the apparently hopeless case of an assistant-surgeon in the army, whose life was thus saved. Dr. Marsh was so struck with the effects of this medicine in the case of a young gentleman residing in the house of the Rev. Mr. Bermingham, Charlemount Mall, that he did not hesitate to my trying the same remedy in the case of Mr. Kerin, then President of the College of Surgeons, whose case seemed to be desperate. Mr. Maturin, son of the celebrated writer, was attacked in the most violent manner, and, indeed, neither I, Mr. McNamara, or Mr. King, had any hopes of his recovery; yet he too was saved. Nothing could be more appalling than the state of Mr. Wilson, of Charlemount Street. The effects of the acetate of lead in his case were so striking, that Mr. Mulock immediately adopted the plan of treatment, and he assures me that he has thereby saved a great number of very bad cases. Dr. Davis, surgeon of the 18th, or Royal Irish regiment of foot, witnessed with extreme interest the acetate of lead tried, and tried successfully, in a very bad case at the Richmond barrack. Equally successful results followed the trial of this remedy in the hands of other practitioners, both in Dublin and various towns in Ireland, during the epidemic of 1834.

After I found out the benefits resulting from the employment of acetate of lead, I no longer desponded when called to cases of cholera, knowing that in the great majority of instances the disease would yield. Of course there are cases of cholera which admit of no treatment, and which an experienced eye will at once recognize as fatal; they occur generally among the aged, or the very young, and are fatal in the course of a few hours, often without any premonitory diarrhœa. But this constitutes no valid objection to the practice; for in what disease do not cases occur which baffle all our efforts? Fever, scarlatina, pneumonia, croup, inflammation of the brain, of the bowels, and many other

affections, occasionally exhibit a degree of intensity which renders them as intractable, and as speedily destructive, as even the worst cases of cholera. But does this occasional intensity and occasional intractability, of certain cases, lead us to regard the diseases above enumerated as beyond the reach of medicine and the control of the physician? By no means; for although we feel our efforts in the particular cases specified to be unavailing, yet we also feel that where the intensity of these diseases is less, we can save numerous lives that would otherwise be lost; so it is, likewise, with cholera.

I may remark, that since 1834, cases of true Asiatic cholera occur sporadically every now and then in Dublin, as I believe happens also in most large towns in Europe once visited by this pestilential epidemic. Of these I have lately seen two decided cases; both were likewise visited by Mr. Mansfield. Both were saved; and yet one was so violent as to have reduced a powerful young man to a state apparently hopeless, in the course of three hours.

I cannot conclude without imploring the profession, in every part of the world where cholera prevails, to give my plan of treatment a fair trial, for I feel confident of its efficacy.

I have the honour to be, sir,

Your obedient servant,

ROBERT J. GRAVES, M.D.

Dublin, Oct. 9th, 1837.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Mediceæ tuæ; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE STARVING EXPERIMENTS.

THE Poor-Law Commissioners, in their experiments on the poor of England, appear to us very much to copy the conduct of Magendie, as described by one of our earlier correspondents. They affect, in their cold-blooded waggery, to be astonished at the writhing of their victims:—"What," they cry, "you

greedy sensualists! are you not satisfied with twelve ounces of bread daily?" Don't you know that Cornaro lived on less? "*Il n'entend pas le Français*," said Magendie, apostrophising an English dog that neglected his admonition not to howl as he was cutting him up alive. They don't know what a nice thing pork-water is, say our Guardians(?) of the poor, in allusion to the complaining subjects of their equally humane experiments.

We shall be thought by many of our readers, and perhaps justly, to belong to the sect of optimists, when we confess that we think it almost impossible for any proved and obvious abuse, in this country at least, to go on without some attempt at a remedy. This is saying, in other words, that we think it impossible that the inquiry into the working of the present Poor-Law, which was broken off by the prorogation of parliament, can remain where it was. The glimpse which it afforded of the real working of this cruel Act must excite every one's curiosity—to say nothing of better feelings—to have a full view of the case; and though Mr. Walter is now unfortunately removed from public life, it is to be hoped that a worthy successor will not be wanting. The oppressed have good reason to exclaim—

Exoriare aliquis vestris ex ossibus ultor!

Mr. Walter's case, it must be admitted, was quite made out. The systematic famishing—the neglect of the sick—the decoying into the manufacturing districts under false pretences—the cruelty to the aged and infants—and the general contempt of all the charities and decencies of life, were, alas! but too easy of proof. Let us recapitulate some of this evidence.

Systematic famishing.—As this is one of the most glaring and sweeping of all the evils introduced by the utilitarian faction in their interpretation of

the new Act, it was natural that all their rhetoric should be employed to varnish it over. Sometimes it is denied altogether, with a coolness worthy of the Central Court, and twelve ounces of bread are asserted to be a very handsome provision; at other times it is alleged that the diet of those confined in a union Bastille ought necessarily to be worse than that of the labourers outside. Now, as no man can tell to what minimum of bread and gruel competition and the fear of the union may drive the labourer, it is clear that the twelve ounces may be abridged to something below even Cornaro's limits. Thus when the victim inside gets his twelve ounces a day, the labourer outside has, we may suppose, thirteen; but competition and the fear of entering the *asylum* compel him likewise to put up with twelve; it will then be necessary to reduce the union allowance to eleven, and so on *ad infinitum*, to the marvellous economy of parochial funds, and great advancement of experimental philosophy!

We showed in our last article on this subject*, that Mr. Mott fell into a strange error in this matter of diet. He thought that persons using little exercise should have from twelve to eighteen ounces of food daily; soldiers and sailors on ordinary peace duty, or labourers, or mechanics, from eighteen to twenty-four; and persons working hard from twenty-four to thirty ounces. So far, however, were Mr. M.'s fancies from the truth, that sailors, as we formerly observed, though included in this second class, have a far better diet than he allows to the third, and are still rather under than over-fed. As to soldiers, Mr. Mott and his coterie are still more grossly in error. We have just seen that he places soldiers in the second class, who ought to consume from eighteen to twenty-four ounces of

food daily. This agrees with the following quotation from a report which we find in a utilitarian print.

"I have shown that the difference in the quantities of food consumed by agricultural labourers and artisans, when procured in return for their labour, as compared with the allowances which persons obtain by becoming inmates of workhouses, prisoners in our gaols, convicted thieves, or transported felons, are as follows:—

"As agricultural labourers . . .	122
As artisans (of the highest wages)	140
As paupers	150
As soldiers	168
As prisoners in gaol	217
As convicts on board the hulks	239
As transported felons or convicts	330."

The diet of soldiers, as given in this quotation, and as Mr. Mott thinks it ought to be, agree together most remarkably; but how do they agree with the reality? Why, not at all. The rations of soldiers are stated as follows, by a much better authority than Mr. Mott, or any of his clique:

"*Mode of living of the soldiers.*—It is unnecessary to enlarge much on this subject, so familiar to every military man. The soldier's ration is, one pound of bread, one pound of meat, and [in certain places abroad] one pint of wine, daily, with two pounds of wood for cooking. He is provided, out of his pay, with a hot breakfast of tea, coffee, or cocoa, and an additional pound of bread previous to his going on duty; at *one*, he has his ration of meat and bread, for dinner*."

Thus we see that, in bread and meat alone, the soldier has twice as much as the utilitarians have assumed: nay, that he has six pounds more in every week than "transported felons or convicts," who, in the above quotation, stand at the head of the eating list, like so many guilty aldermen!

There is a pleasant story in the books of a highwayman who saved his

* Vol. xx. p. 357.

* Hennen's Sketches of the Medical Topography of the Mediterranean, p. 218.

neck by a most elaborate artifice. The prosecutor swore that the robbery had been committed while the moon was shining brightly; but on the prisoner's counsel handing up an almanack to the judge, it appeared that the moon did not shine at all on the night of the robbery. The almanack had been printed for the occasion! We do not think, however, that the Poor-Law people, who are now on their trial at the bar of public opinion, will be able to escape from their uncomfortable predicament by a similar stratagem. It is in vain that they print their dark almanacks—in vain that they tell us of accetic soldiers and sailors (*pour encourager les autres*,)—in vain that they garble the letters addressed to them*, and attribute every casual improvement to the fear of their gruel-houses,—the people of England cannot be gulled in this manner; and either the evil must be remedied, and the huge lie swept away, or the growing estrangement of the poorer from their more opulent classes will produce consequences which we shrink from describing.

In the Report of the Select Committee, it appears, from the evidence of Mr. James Lambert (who was governor of Westhampnett Workhouse, from Nov. 3d, 1832, to March 1st, 1836,) that as soon as the new diet table came into operation, the weekly allowance of bread was reduced from 126 ounces to 78; of meat-pudding, from 20 ounces to 14; of suet-pudding, increased from 20 ounces to 28½. So that the experimentalists had reduced the daily slice of bread to even less than twelve ounces! This gave

rise to a curious scene. One of the starved came before the Board of tormentors with his bit of bread in his hand; and our readers will naturally suppose, that the very sight of such a mouthful would be a sufficient answer to the shameless assertions and falsified tables of the utilitarians. "The bell rang," says Mr. Lambert, in his evidence, "and the Duke of Richmond asked me, if that was all the bread I gave to this man; I answered, 'Yes, I think it is, by what I can see.' The Duke asked me how much it should weigh; I said, 'Twelve ounces, when I gave it to him.' And he said, 'Fetch me your weights and scales;' and I did so. I put it in, and it weighed twelve ounces. The man made an answer, and said, 'Do you think this is enough for a man to work with all through?' The Duke said, he could not give him any more, as that was what the diet-table expressed, and that was all; but the man made answer and said, that it was not so much as he had in Petworth gaol*."

Neglect of the sick.—Under this head it would be sufficient to allege the perverse ingenuity of the Commissioners in obtaining medical men at the cheapest rate, without regard to any but the technical qualifications; well knowing that the rate is often so low as not to cover even the expense of proper drugs; we have often alluded to this part of the subject before, and at some length; but we think it right just to mention the case of Honor Shawyer. This unfortunate woman died of mortification of the bowels in Bishop's Waltham Workhouse; and though the grossest neglect had been made out against the master and mistress of this receptacle, and formally presented in the Coroner's

* Mr. Dainty, clerk of the Petworth Union, in a letter to Assistant-Commissioner Hawley, after speaking of an improvement in the conduct of the poor, says: "I must add, that many circumstances have occurred in tending to produce the effects I have described: the first is the establishment of an active and efficient police in the town of Petworth." But Mr. Hawley omitted this passage, because, he says the police in the town of Petworth could have nothing to do with the parishes in the Petworth Union! (First Report, p. 61.)

† Seventeenth Report, p. 66.

* Seventeenth Report, p. 17.

From the subsequent answers of Mr. Lambert, it appears doubtful whether the man said that it was not so much as he had in Petworth gaol, or not so much as *those* had who were confined in Petworth gaol.

inquest on Honor Shawyer, they were not dismissed from their situations until seven weeks afterwards. They were succeeded by John Murphy; and so little impression had been made upon the experimentalists by this lamentable case—so little disposed were they to return to the paths of humanity, that it was during Murphy's mastership, but against his wish, that the famous attempt was made to give the paupers in Bishop's Waltham Workhouse pork-water for soup, and puddings made of the skimmings of pork-water instead of suet*. The Rev. Mr. Brock, seeing how the sick were neglected, used to send them food from his own house; for which he was found fault with by the *Guardians*, and called meddling and officious†.

Decoying into manufacturing districts.—Among other whims and oddities of the Commissioners, they imagined that they were qualified to regulate and equalize the labour-market all over England; and accordingly endeavoured to transfer the victims of their experiments from the agricultural to the manufacturing districts. The case of poor Sopp, whom they transplanted in this manner, will occur to many of our readers. To aid the scheme, one Muggeridge, who is called a migration agent, sends from Manchester the price-lists of a puffing shop-keeper; and though they would hardly take in any reasonable person, yet they might easily impose on a famished labourer, ready to catch at a straw. Thus, for instance, the Manchester advertiser tells us that he sells—Men's trowsers, fustian, from 1s. 10d.; beaverteen, from 3s.; beaverteen lined, from 4s.; moleskin, from 4s. 9d.‡ Is there any one but Muggeridge who does not know that lists of this

kind, in which the lowest prices only are mentioned, are purely deceptive; and that the trowsers in question (if at all forthcoming) would be, like Peter Pindar's razors, made only to sell? If the man does not know this, instead of being fit to be a "migration agent," he is hardly fit to walk about by himself.

Cruelty to children and the aged.—

Three children, between four and five years of age, named Withers, Cook, and Warren, were sent to the Fareham from the Bishop's Waltham Workhouse. One remained in his new abode for twelve weeks, the other two for eight weeks each. Mr. Wm. Harrison, the master of the Bishop's Waltham Workhouse, describes their state when they returned. They were standing against the wall in a passage; he desired them to walk into a room; they attempted, but could not. It was a cold day moreover, and they were without proper clothing. After about a quarter of an hour, food was offered them, which Warren vomited up again. It appears, that during their stay in Fareham Workhouse, in order to cure their dirty habits, these miserable infants had been additionally starved, flogged, and placed in the stocks—sometimes from 9 to 12, and from 2 to 5. One of them had a prolapsus ani*.

This monstrous case was rather too bad, even for the Poor-Law Commissioners; if they had no compassion, they had some fear of public indignation, and accordingly reproofs were dealt forth to all the persons concerned in tormenting these poor little creatures. The misfortune is, that every one suspects that the rigour of the Fareham people proceeded in part from their desire of acting up to the spirit of the new law, and consequently the Commissioners do not get all the credit they could wish for their humane reproofs. It is so loudly avowed, say the censo-

* Third Report, p. 43.

rious, that to make the poor systematically uncomfortable is the object of the Union receptacles, that it cannot be wondered at if the directors of these fastnesses sometimes overshoot the mark, and worry their inmates to a degree that cannot be publicly defended.

Nor has the other extremity of life been a protection from the rigour of the new regulations. Jas. Sparshott, *aged ninety-one*, had his allowance reduced from three shillings and sixpence to half-a-crown a week*. The Rev. Mr. Spencer, indeed, Chairman to the Board of Guardians of the Bath Union, and a starvationist of the first water, speaks with indignation of a pauper, aged 84, who refuses to reside in the workhouse, as well as of certain mischievous ladies who not only abet and comfort him in this his nefarious obstinacy, but actually give him a weekly allowance!† Our austere chairman says, that rather than be washed, shaved, and have his hair cut, many a pauper has gone away from the workhouse. Perhaps this aversion to being shaved, Mr. Chairman, may arise from your shaving them so very close.

We will proceed with the other articles of our charge in a future number.

ST. GEORGE'S HOSPITAL.

ABSTRACT OF A CLINICAL LECTURE ON DISEASE OF THE KIDNEY,

Delivered Oct. 10, 1837,

By SIR B. C. BRODIE, BART.

SIR BENJAMIN BRODIE commenced his course of Lectures on Clinical Surgery at the usual hour (half-past one.) He began by stating, that he would not trouble the class with any thing in the shape of an introductory lecture, as they had probably heard the subjects of such addresses already sufficiently dwelt upon elsewhere. He would only observe, that the course

was necessarily limited by the number of weeks in the medical session, and that, as he was anxious to make it as useful as possible, he should select for illustration those points which were calculated to afford the greatest amount of practical information. Now these would be found to consist, not in the rarer or greater cases merely, but would also comprehend a due attention to the smaller points in surgery, which gained in importance from their frequency what the others did from their magnitude. He should chiefly connect his lectures with cases in the hospital, but would occasionally devote two or three lectures to any particular subject which he was desirous of illustrating, or which they themselves might wish to have explained to them. He wished the pupils to talk together about the cases, and to agree upon those points on which they required farther information; he would always be happy to attend, as far as possible, to their wishes in this respect; and he meant the observation to apply to the junior pupils as much as to the senior, for they had an equal right to have their interests attended to, and the hospital practice made as useful as possible to them.

He had been absent for some weeks, and had not had an opportunity of becoming acquainted with the cases; but his clerk had put one into his hands, which seemed well calculated to be the text of some remarks.

James Lambert, *ætat.* 40, admitted September 20, 1837. Complaints of pain in the region of the bladder, which first came on ten weeks ago, when he likewise perceived the urine to be muddy, with a thick sediment. The pain is most severe when the urine contains the largest quantity of sediment; and it then extends to the loins and thighs. The flow of urine often stops suddenly, and this is followed by cutting pain in the urethra; after which he cannot make water for more than half an hour. Has never passed blood, but there is a white purulent deposit in the urine, which is albuminous; has no stricture.

Infus. Diosmæ, ʒiiss. ter die. C.C. Lumbis, ad ʒx.

Pain in the loins was relieved by the cupping.

25th.—Urine became a little clearer, but this lasted only for a short time.

Morphiæ Acet. gr. ʒ, 8vis horis. Extract Colocynth. C. gr. v. om. nocte.

Oct. 8th.—No change.—*Omitt. Morph.*

The prominent symptoms here were—the frequent desire to make water, the pain referred to the penis and urethra in voiding it, and the purulent deposit in the urine. The urine, it was farther to be

* Tenth Report, p. 21.

† Second Report of the Poor-Law Commissioners.

remarked, was acid and albuminous. Its acidity was proved by its reddening litmus paper; and the albuminous character shewn by its dropping a coagulum on the addition of nitric acid. There had been pain in the loin, and down the inside of the thigh. Now this was just such a case as used formerly to be referred to irritable bladder, but he believed it would be found to depend upon disease of the kidney. When he began practice, a patient with such symptoms used to be examined to see if he had any stricture or enlargement of the prostate gland, and it was also inquired whether he had any appearance of calculus; and if he had none of these, it was then thought that the case was sufficiently explained by calling it one of "irritable bladder."

He had, many years ago, attended a lady who voided her urine in small quantities, with a severe pain in the urethra, &c. and he had sounded her more than once, supposing there might be a calculus in the bladder, but without finding any. None of the remedies used were of much avail, but some time afterwards she was seized with pain in the course of the ureter, which suddenly ceased, and next day she voided a mulberry calculus, from which time the symptoms were relieved. In this case there can be no doubt but that the symptoms, which were referred entirely to the bladder, depended upon the lodgement of a calculus in the kidney. He attended a gentleman whose bladder could not retain above a table spoonful of water; the urine was albuminous and purulent. No stricture of the urethra existed, and there was no stone to be found in the bladder. In this case, too, the remedies proved inefficient: at last he was seized with pain in the course of the ureter, extending to the bladder, and followed by the expulsion of a solid portion of lymph, with a fimbriated extremity. He had several similar attacks, and under one of these he died in the country.

Morgagni relates a case of this kind.—A boy had pain referred to the urethra and bladder, with inability to retain his urine; he died, and on examination after death, the urethra, prostate, and bladder, were found to be healthy, but there was a stone in the kidney. Sir Benjamin had himself seen several cases more or less similar—that is to say, in which symptoms referred to the bladder had been proved to depend upon disease in the kidney. He had attended a patient who laboured under frequent desire to make water, pain in the urethra and neck of the bladder, and albuminous urine, and who ultimately died with disease in the kidneys, and none in the bladder.

In another case the patient had similar symptoms, and died from a cause foreign to urinary disease—namely, from bursting

of the gall-bladder, and subsequent peritoneal inflammation, for which he was attended by Dr. James Johnson. Now here there were found a dark coloured and spongy condition of the kidney, with deposits under its external coat of bodies of transparent appearance, resembling hydatids, though essentially different in character, while the tunic of the kidney adhered so firmly to the fat of the loins as to remain *in situ*, while the kidney was peeled out from it. The bladder was free from disease, although all the symptoms had been referred to it and the urethra.

But it is only when patients labouring under disease of the kidneys die early—cut off as it were by some accidental occurrence, that the dependence of the symptoms exclusively on such affection of the kidney can be proved, because disease of one part of the urinary system soon brings on disease of other parts. One of the first of such extensions is to the bladder, the mucous membrane of which becomes irritated by the morbid state of the urine, and then inflamed; being once inflamed, it in its turn secretes aropy tenacious mucus, which sticks like bird-lime to the interior of the vessel into which it is voided. Portions of phosphate of lime frequently show themselves; and now the urine becomes alkaline, and is often extremely fetid.

But another and peculiar circumstance which sometimes attends disease originating in the kidney, is abscess at the neck of the bladder. Sir Benjamin has seen several examples of this—i. e. of patients having disease of the kidneys, whether suppuration, calculus, or other change, becoming affected with abscess at the neck of the bladder, and in one such he had opened the abscess in the perineum, and evacuated a large quantity of pus, the probe passing into an extensive ulcerated cavity connected with the prostate gland. Perhaps this phenomenon was explicable on the principle of the nerves of the part being in a constant state of irritation,—a condition which, under other circumstances, was productive of inflammation and its consequences. Thus he remembered that in the case of the late Dr. Peimberton the face was swollen on the side where he had suffered most from pain. Now his disease was an aggravated instance of the *tic douloureux*, and Sir Benjamin inferred that the excited state of the nerves had, after a certain time, led to inflammation in the cellular tissue of the parts. So, likewise, with regard to abscess which formed at the neck of the bladder in disease of the kidney. The nerves were then in a state of constant irritation, as indicated by the inability to retain the urine, and this, in some constitutions, was productive of inflammatory

action on the contiguous parts, ending in suppuration.

With regard to the kind of disease which took place in the kidney in such cases as he was considering, Sir Benjamin did not think that it was necessarily always the same. Sometimes it seemed to be a form of chronic inflammation, either limited to the tubular part of the gland, or pervading its whole structure: sometimes there appeared to be distinct abscess formed; at others the pus would rather appear to be formed by the lining membrane, without any ulceration. Sometimes there was calculus impacted in the kidney: sometimes there were those serous cysts to which he had already alluded; and sometimes the gland was altogether converted into a collection of cysts or vesicles, the glandular structure being nearly or wholly destroyed.

The symptoms which characterised disease of the kidney at its early stage, such as the case before them, were pain referred to the penis and urethra, with incontinence of urine, so that the patient is obliged to void it sometimes so frequently as every half hour; uneasiness, sometimes amounting to pain, in the region of the bladder itself; and occasionally, but not necessarily, pain in the loins, or in one loin, corresponding to the diseased kidney. The urine at this period is sometimes quite clear and healthy, at least it is at times free from albumen, but always becomes opalescent sooner or later, and coagulates on testing it with nitric acid.

To these symptoms at a more advanced stage become added paroxysms of pain, extending from the kidney to the bladder, with affection of the testicle or inside of the thigh. The urine also contains pus; and when this comes suddenly in considerable quantity, and afterwards nearly disappears, it may be conjectured that it is from an abscess. But in other cases pus continues long to show itself as a deposit in the urine, without the symptoms of abscess, and is probably secreted by the kidney without abrasion of surface. Frequently, as in the case before them, there was a deposit of purulent matter; and whether this were so or not, it was acid and albuminous; not that it invariably had these last characters, but they were always present at times in the course of the disease.

Then the urine is usually possessed of another and very peculiar character in its smell. No peculiarity of this kind admits of description; but of the familiar odours which it most resembled, that of musk came nearest. Now this musk-like odour must not be confounded with that which arises from mucus secreted in the bladder; this last is ammoniacal, and the urine often absolutely stinks. This

latter state is owing to inflammation of the mucous membrane of the bladder, and the decomposition of its secretions, so as to evolve ammonia.

With respect to treatment: one of the most distressing circumstances was the inability to retain the urine, from the irritability of the bladder, which, as already stated, was sometimes intolerant of half an ounce of that fluid. Now something might be done to relieve both this and the pain accompanying it, by the use of opiates; but he was, upon the whole, averse to these, as they sooner or later interfered with the functions of the stomach, which it was of great importance in these cases to cherish: besides which, the opium had no tendency to cure the disease eventually. He therefore limited his patients to a suppository of opium introduced into the rectum, or a clyster at night. In regard to the power of the bladder, he had known a patient improve this by accustoming it to the presence of quantities gradually increased: he had injected two ounces of tepid water, and, persuading the bladder to retain that, had increased the injection to half a pint; thus, by perseverance, enabling the bladder to acquire better habits, so that he was able to go into society, which he had previously been prevented from doing. But those two (the opiates and injections), where it was expedient to try the latter, could only be looked upon as palliative means. Considering the symptoms during life, and the result of post-mortem examinations, there was reason to regard such cases as very generally connected with inflammation about the kidney; and in keeping with this, was the fact that he had seen considerable and permanent relief from counter irritation being established in the loins, either by means of a seton or caustic issue. He had also seen blistering of much service.

As to internal remedies more particularly directed against the disease, he thought that a distinction was to be made between the condition of the bladder often consequent upon disease of the kidney, and original disease of the latter. The former, when attended with secretion ofropy alkaline mucus, was frequently much benefited by the *Pareira brava*; but this had little if any effect on the kidney. In the case before them, the decoction of the *Diosma* had been ordered, in doses of $\mathfrak{z}\text{ss}$. three times a-day. This was a remedy from which he had repeatedly seen unequivocal benefit in such cases; and another which also occasionally proved of service, was the *Uva ursi*, but for this purpose it required to be given in much larger doses than those usually administered; perhaps the best form was a decoction of $\mathfrak{z}\text{ss}$. or $\mathfrak{z}\text{j}$. in 6 oz. of water. There was a popular medicine, too, which he would

mention, though it had not found its way into the Pharmacopœia: he meant the seeds of the wild carrot. This plant, which had long been used for such purpose among the people, was always kept at Covent Garden, though not to be had at the druggists.

The hour having expired, prevented Sir Benjamin from concluding the subject in the present lecture.

HÔPITAL DE LA PITIÉ.

SECOND SERIES OF CASES*.

CASE I. — *Pleurisy, with Effusion.*

AN ironmonger, aged 32, of a strong constitution, was admitted a patient, under M. Louis, January 17th.

He has lived freely, and is generally tipsy once a week, and is subject to epistaxis. He has been ill six weeks. His illness commenced with a pain in the right side; fifteen days afterwards he had a cough, with fever, so as to be confined to his room: the fever has continued from that time, and the pain has never left him. He has never expectorated blood, nor been subject to cold.

18th.—Countenance bloated; skin moist and warm; pulse 96 yesterday evening, 62 this morning; anxious; thirst; no headache; lies with most ease on the left side, more so than on the back; tongue moist, and whitish; sputa clear. Percussion loud under both clavicles; dull below the right mamma; dull posteriorly in the inferior half of the right side; in the latter situation the respiration is nearly inaudible, but there is no ægophony or bronchophony. Sounds of the heart very distinct.

Potass. Acet. ʒss. in Mist. Mucilaginis. Venæsectio ad ʒx. Low diet.

19th.—Coagulum firm, and covered with a grey coat; less cough; slept well; tongue white; respiration dry and harsh under the right clavicle. No other change since yesterday.

Rep. Mist. Potassæ Acet. Pulv. Digitalis, gr. j.

21st.—Pulse 64. Less cough; tongue natural. The same dull sound on the right side posteriorly; respiration weak posteriorly, absent inferiorly, on the right side. No irregular bruit. Has had a pain in the left side since yesterday.

24th.—Pulse 72; no expectoration. Very little difference between the sounds on percussion posteriorly, but the respiration is rather weaker on the right side. In a few days he was able to leave the hospital.

REMARKS.—The general symptoms were

not, in this case, sufficiently acute to be the consequence of a pneumonia of so great an extent; besides, there was complete absence of crepitation and the characteristic sputa. Bronchophony would also have been heard. The dulness upon the right side must, then, be attributed to inflammation of the pleura, which was approaching its termination when the patient was admitted. As there was no ægophony, M. Louis gave it as his opinion that but little fluid had been effused, but that false membranes had been formed. There was no reason, either from the history of the case or from the local signs, to suppose the existence of tubercles; but a few days before he left the hospital, he complained of a pain in the left side. Should this pain return, the existence of tubercles in the lungs would be rendered very probable, as it is very rare to see idiopathic pleurisy attack, at the same time, both sides of the chest, while it is comparatively common when produced by tubercles.

CASE II. — *Pleurisy with Effusion. — Emphysema.*

A man, aged 30, of a strong constitution, was admitted a patient, under M. Louis, March 2d.

He has resided in Paris several years, and always enjoyed good health. His present illness commenced a fortnight ago, previous to which time he had not the slightest ailment. His work is not laborious, but the day he was taken ill he worked more than usual. In the evening a pain came on under the left mamma, which has continued since, but not very acute. He had a little fever also, but was not prevented from pursuing his occupation; his strength, however, failed him, and he lost his appetite. Two days before his admission the pain became more acute, accompanied with cough and considerable dyspnoea.

3d.—His face is pale; heat of skin natural; pain in the side not very acute; pulse 88; respiration 24; percussion dull posteriorly, on the left side, in the three inferior fourths; bronchophony and bronchial respiration in the whole extent. When placed on his abdomen, the sound is clear and loud, and the bronchial respiration ceases, but the voice resounds still in parts, and very distinctly just below the angle of the scapula.

Ptisan. Venæsectio ad ʒxiv. Low diet.

4th.—Pain and dyspnoea relieved three hours after the bleeding, but he bore the loss of blood badly. Coagulum not very firm, without any coat, and covered with much serum. Pulse 88; no headache; heat of skin natural. Complete dulness

* The first series was given in our last volume.

upon percussion in the three inferior fourths of the left side; bronchophony to within four inches of the summit, but less marked inferiorly. Percussion and respiration natural on the right side. Anteriorly, percussion is louder for some extent under the left clavicle than on the opposite side, and the respiratory murmur is weaker; below the left mamma percussion is dull. Above the left mamma, the chest projects slightly, and the intercostal spaces are nearly obliterated. Pulsations of the heart feeble. He had never been subject to dyspnoea.

Acet. Potass. 3ss. to be put in the Ptsan. Pulv. Digitalis, gr. j.

6th.—Dyspnoea considerably relieved; the local signs remain the same. After lying on his belly a minute or two, the percussion is not so dull, but the difference is not so great as on the first day. No appetite.

Pulv. Digitalis, gr. j. bis in die.

On the 7th he took four gains of digitalis daily; on the 9th, five. On the 14th he vomited a greenish fluid; had two or three stools; percussion yielded more sound under the left mamma, where there was distinct crepitation. On the 21st, there was crepitation posteriorly on the left side, with a little bruit de frottement, but percussion continued dull: his appetite had returned. On the 25th he was on full diet; the dullness persisted posteriorly; there was fine crepitation in the inferior third; a little bronchophony in the middle third, also at the very inferior part of the axilla, where crepitation was also heard. On the 27th he left the hospital, his general health being quite re-established.

REMARKS.—The diagnosis of this case was very easy, though at the commencement there might have been some difficulty in distinguishing it from pleurodynia; as the pain was unaccompanied by cough, fever, or diminution of strength. The prominence of the chest anteriorly on the left side—the slight depression of the intercostal muscles—the obscure respiratory murmur—the loud percussion, and that, too, on the side of the effusion—all denoted the existence of emphysema. The patient had never been subject to dyspnoea. This is only the third case which has fallen under M. Louis' notice, where emphysema has existed unattended by dyspnoea.

M. Louis does not regard pleurisy when simple and uncomplicated, and when it does not occur in an aged individual, as a dangerous disease. Indeed, under these circumstances, he has never seen it fatal, though above 150 cases have been treated and recorded by him. His treatment consists of one or two bleedings at the com-

mencement, and in the administration of diuretics. Patients affected with pleurisy seldom apply for admission into an hospital so early as those attacked with pneumonia, and require less energetic treatment.

Cases of fractured ribs are almost always accompanied by some degree of pleurisy, and yet unless the lung is extensively lacerated, and there are other severe injuries, they rarely prove fatal. Thus, out of about 200 cases admitted into the London Hospital during the last two years, twelve only have died. Of these, eight were above sixty years of age, and three above fifty. In three others, injuries existed sufficient to cause death. In seven the lung was extensively lacerated, and several ribs were fractured. In two only was pleurisy the cause of death. One was aged fifty, and died on the ninth day; the other was aged sixty-eight, and died on the third day.

Towards the termination of the inflammation in the preceding case, crepitation was distinctly heard on the left side. M. Louis attributed this noise to the friction of false membranes imperfectly organized. The same bruit is often heard in cases of pneumonia, when they are convalescent, and which is most likely caused by the same lesion*. False membranes often present a reticulated appearance, and we can easily believe that the friction would produce a sound very similar to crepitation.

CASE III. — *Vesicular and Interlobular Emphysema.*

A very intelligent sailor, aged 56, of a strong constitution, entered the hospital April 5th. When admitted he had a little fever, much dyspnoea, and cough, with subcrepitation on both sides, posteriorly. He was bled, but without relief; some laudanum was given, and his breathing became easier. He was left-handed, on account of a wound he had received in the right shoulder. Four or five years ago, after making a violent effort in a trial of feats and strength, he had a hernia on the left side, and suddenly a difficulty of breathing, which has continued to the present time, with frequent accessions of dyspnoea and palpitations, during the last two years. Previous to this exertion his breathing was quite free. Since this time he has been very subject to colds and coughs.

April 8th. — Countenance natural; dyspnoea diminished; chest well formed; a projection on the left side, extending from a little below the mamma to

* No allusion is here made to the crepitation *redax* of Laennec, which depends upon engorgement of the lung.

within an inch of the clavicle; a similar projection on the right side, but not so great. The projection on the left side is partly due to a greater development of the pectoralis major muscle: the left shoulder is also a little more elevated than the right. Percussion clear and loud anteriorly, but particularly so in the precordial region. Respiration natural, but weaker in the same region. Posteriorly, percussion is loud; on the left side the respiratory murmur is feeble. A little subcrepitation on the left side inferiorly; more on the right. A little below the left mamma, anteriorly and laterally, a bruit de frottement is heard; the pulsations of the heart are inaudible; no œdema; palpitations frequent; digestive functions healthy; pulse regular.

REMARKS.—The accidents more frequently caused by a sudden strain in which dyspnœa and palpitations are present, are rupture of vessels and aneurisms. In one man examined by M. Louis, who, after a sudden strain, had dyspnœa, palpitations, and a bruit de lime, the aortic orifice was found very much contracted. Aneurisms, however, are generally the result, very often at the origin of aorta, where they are more difficult to detect, and generally prove fatal in a shorter period.

The pulse in this case was regular; there was no impulsion—no abnormal bruit; the sounds of the heart could not even be heard, so that the dyspnœa and palpitations could neither be attributed to aneurism nor contraction of the aortic orifice. The projection on the left side, the loud sound upon percussion even through the thick muscular parietes, the feeble respiration, the dyspnœa, the subcrepitation, indicated the existence of emphysema caused by the rupture of some air-cells at the time of the effort. The peculiar bruit de frottement renders the existence of *interlobular* emphysema very probable, as that is generally accompanied by some bruit.

The patient soon left the hospital much relieved, having taken small doses of opium.

improvements introduced by Mr. Key, whose proposition of operating without opening the sac should not be looked upon as a mere revival of an old idea, since obsolete works, in alluding to the subject, advised such an operation from mere mechanical views, dreading the descent of a great quantity of intestine if the sac were opened in large herniæ; but Mr. Key looked upon the opening of the peritoneal cavity as the great source of danger; and this he hoped to obviate, in many instances, by dividing the stricture outside the sac. Mr. C. stated that he had performed the operation seven times. Six out of the seven instances were successful: the seventh was a case in which the operation was not permitted till strangulation had existed for so long a time that recovery was almost hopeless under any circumstances. Mr. C. advised the administration of small doses of sulphate of magnesia at intervals, after the operation.

In answer to questions from various gentlemen, Mr. C. strongly deprecated the use of tobacco injection, recommending bleeding in the erect posture as a substitute. He stated the case of a robust woman, which occurred several years ago, in Norfolk, and terminated fatally in twenty-five minutes, from the use of a tobacco injection, made with half a drachm of the tobacco leaves. His reason for exhibiting saline purgatives was to induce a healthy peristaltic motion in the intestine just relieved from strangulation; this motion he considered as calculated to produce a return of the natural secretion of the intestines.

At the close of the meeting a vote of thanks to Mr. Cooper, for his valuable communication, was unanimously carried, on the motion of Mr. Dendy, seconded by Mr. Iliff.

At the next meeting of the Society, on the 21st instant, Mr. Aston Key in the chair, Dr. Guy will read a paper *On the Effects of Posture on the Pulse*.

WESTMINSTER HOSPITAL.

Severe Cut Throat.

WILLIAM LYNCH BOOTH, æt. 21, whose tattooed skin and hard hands indicated his rank to be plebeian, was admitted on the 4th September, 1837, having inflicted a severe wound on his own person. Passing by a butcher's shop, he suddenly rushed into it, and seizing a knife, drew it across his throat. The edge of the knife passed between the os hyoides and thyroid cartilage, and divided the anterior half of the pharynx. He had fainted from loss of

GUY'S HOSPITAL.

PHYSICAL SOCIETY.

THE first meeting of the Physical Society of Guy's Hospital, for the present session, took place on the 7th instant, Dr. Addison in the chair; when Mr. Bransby B. Cooper read a paper *On Hernia*.

The chief points alluded to by that gentleman were—1st, the advantages to be derived from a correct knowledge of the anatomy of the fascia transversalis, as described by Sir A. Cooper; and 2d, the

blood, and was insensible when brought into the surgery. The thyroïd arteries had been divided, but the carotids were safe. He was placed on his side, a position which he preferred, and simple pledgets were laid over the wound.

Next morning (5th Sept.) Mr. White endeavoured, but without success, to introduce an elastic tube through the nose into the stomach. A violent spasm foiled the attempt. He, however, succeeded in passing the instrument through the wound into the œsophagus, and thus formed a channel through which beef-tea and thick nutritious fluids were conveyed into the stomach. During the whole of the 5th the man was quiet, but at night a paroxysm of delirium supervened; hence it became necessary to fasten his hands and feet.

9th.—Each succeeding day he was perfectly quiescent till evening, when the delirium returned with almost maniacal violence. Last evening the usual paroxysm came on at about nine o'clock, and continued with undiminished violence till one A.M., when he became tranquil. At four A.M., three hours after this change, he expired suddenly.

During the day-time his pulse was quiet, and generally numbered between 80 and 90, but at night, immediately after the exacerbation, it reached to 150 beats. At these times the animal heat was also increased. His bowels were acted upon every morning by means of a clyster. In the intervals of the paroxysms he was rational. He could articulate words in a whisper, but there was no vocalization of sound. He generally preferred making known his wants by writing.

An examination of the body was made a few hours after death. All the viscera of the great cavities were apparently healthy. The brain offered no pathological characters; but in the cerebellum the medullary part was tinged of a uniform and homogeneous pink colour, not arising from any obvious injection of vessels. The edge of the wound was covered with lymph and exsiccated mucus, and signs of œdema were obvious in the tissues adjacent to the glottis, which, had the patient lived long enough, would have destroyed him. No injury was inflicted on the glottis by the knife, which had made a clean cut between it and the epiglottis.

It appears that when a cloth was placed over the wound, the patient had the power to vocalize imperfectly; but when the cloth was removed, though the breath passed through the mouth in sufficient quantity to enable him to whisper audibly, yet none of the vowel qualities could be produced.

APOTHECARIES' HALL.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

*At the Anatomical School, Kinnerton-Street,
near St George's Hospital,*

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE IV.

Physical Examination of the Chest—Modes of Studying the Topography of Organs—Examination of the Chest by inspection and feeling—Natural form of the Chest—Postures for inspection—Examination of the motions of the Chest by sight and touch—Varieties of Respiration—Menturation of the Chest—Measurement of the Air respired—Limitation of the Signs obtained by sight and touch—Need of another Sense—Modes of Studying the Acoustic Phenomena of the Chest.

HAVING now anatomically and physiologically gone through the general structure, functions, and relations of the chest and its organs, we have next to study these subjects as physicians; and you will immediately see how essential our previous knowledge is to prepare us for this study. We have to find out the signs or symptoms through which, in the living body, we can judge of the condition of the various parts of the structure, and of the performance of their several functions, and thus through which we can distinguish health and disease. This department we will, if you please, call EXAMINATION OF

THE CHEST; for although it is the organs within it, rather than the chest itself, which we generally wish to study, we must never forget that the chest is, as it were, an outer coat of these organs, fitted to them, and partaking of their shape, motions, and sensibilities; and as in health these all work and feel together, so in disease we must never lose sight of their mutual dependencies and connexions. Now as we have considered the properties of the chest and its organs under the two heads, physical and vital, so you see that in my prospectus I divide *Examination of the Chest* into two kinds:—1. As practised PHYSICALLY by vision, tact, and hearing;—2. THROUGH FUNCTIONS, or through those more complex properties or actions which depend on vitality superadded to physical structure. These two kinds, although studied separately, must be used conjointly.

We examine the chest PHYSICALLY, through those properties of form, size, proportions, and relative position of its parts, at rest and in motion, which are appreciable by our external senses. Now, gentlemen, mark me; you cannot get on well in the physical examination of the chest without a topographic knowledge of the organs within it: you must know where each severally lies and reaches with regard to the exterior, so that when you inspect, feel, and listen to the chest, you may be able to map out the general outlines of the organs within.

You will ask me, how are we to get this knowledge? There are two ways to it; and I would advise you to use them both. The first and most obvious one is, by attentively observing, every time you see a body opened, the position which the organs hold with regard to the exterior. The minutes which we are apt to consider as time lost, while we are impatiently waiting to see the morbid anatomy within, may be profitably employed in taking

a lesson of the anatomy of position. As the dissector's knife cuts the integuments, our eyes may rapidly survey certain external marks which we may be ready to compare with the interior when it shall be opened. There are the nipples, the edges of the pectoral and serrated muscles, the intercostal spaces, which can generally be counted with ease near the sternum, the divisions of this bone, the clavicles and scapulae, and divers minor elevations and depressions on the exterior, all of which may serve as landmarks to indicate the positions or boundaries of the organs and their several parts. The moment the sternum is raised, and before the lungs collapse (which may be prevented by closing the nostrils,) we can glance at the extent to which these organs cover the heart and reach downwards, the position of the air and blood vessels, the height of the diaphragm, and the abdominal viscera beneath, and we can transfer these various sites to some of the marks or lines of the exterior.

I do not mean to assert that this habit of comparison of the outside with the inside in the dead body will give you a very accurate knowledge of what exists in the bodies of the living; for besides that there is some variety in different individuals, there can be no doubt that on the motions and properties of life being destroyed, some changes may consequently take place in the size and relative position of the organs, and these may vary according to the mode of death. Thus it is probable that the diaphragm, relaxed by death, permits the abdominal viscera to encroach on the cavity of the chest further than during life; and the volume and position of the heart and lungs will be affected not only by this circumstance, but by the condition of the circulation and respiration at the time of death, and by the influence of time and temperature on the stiffening of the muscles, and other changes which immediately succeed death. These are subjects which deserve further investigation. In spite of these exceptions, which it is well to be aware of, I repeat that you may gain much valuable knowledge of the topography of organs in the way that I have described, and this knowledge will be of such a personal, practical kind, that it will gradually confer on you a self-correcting tact and insight which you can never gain from mere rules and descriptions.

There is another way to the knowledge of the topography of organs; it is more exact, but more difficult. It is the *habit* of physical examination; and thus our study enlightens itself. We cannot dwell on this now, because it comprehends the details which will occupy us for several succeeding lectures; but I will tell you,

by way of encouragement, that after you have carefully examined half a dozen subjects, by the different physical means which we have now to explain, you will have gained results which may supply you with a good general idea of the topography of the living chest. In short, it comes to this—practice alone can make you perfect in this, as in every other study in which the senses are to be exercised.

I have attempted in these diagrams to set before you views of the topography of the pectoral organs, and by giving a transparency both to the chest itself, and also to the viscera, I have endeavoured to represent their form, size, and relative position. Here, for instance, is an external front view of the trunk of a man: it is sketched, as you see, in Indian ink, with all the points, prominences, and depressions, which are presented in the natural contour of the body. But through this exterior you see the lungs, the heart, the liver, the stomach, the spleen, &c. tinted in different colours, and by a convenient transparency in these viscera, you get a general view of the interior—how the several large vessels pass, and how one organ is superposed over another. Thus, here are the lungs with the large bronchi, coloured light pink, and the liver purple; and where at the margin of the diaphragm the latter of these viscera comes in contact with the external parietes, its colour is deep and distinct; but where it rises above into the vaulted hollow of the diaphragm, it is seen in a fainter colour, because it is gradually shaded off by the superjacent light coloured lung. So also the heart, in the small space in which it comes in contact with the chest to the left of the lower end of the sternum, has its crimson colour; but it also communicates its tint more faintly through the lungs which lie over its whole body, and the vessels which proceed from it, and so on with other organs. Here is another diagram representing the back view of the chest and abdomen. [These diagrams cannot be given in print.]

Now you are not to suppose that these drawings give a very exact view of pectoral topography, for, as I have said before, the parts and their outlines are to a certain extent variable and shifting; but they will assist you in the two other modes of study which I have pointed out, and they will be of material service to us in our explanations of various diagnostic phenomena of health and disease. You may, too, if you please, take from them the idea of transparency; and when you examine a chest, try, in a study of external marks, to see the outlines and positions of the organs within.

Well, now let us touch lightly on the

examination of the chest by sight and feeling. The patient standing, or sitting even, with his arms and legs in corresponding positions, and his chest, if possible entirely exposed in a good light, we view it in front, behind, and from above, and mark its form and proportions, and corresponding prominences and depressions. A healthy chest is very nearly symmetrical, the two sides corresponding in shape and size. The right side is, however, almost always slightly larger than the left, especially at its lower portion, where the difference of measured circumference amounts generally to half an inch. This preponderance in favour of the right side is in part to be ascribed to its contents, but it is chiefly connected with a law which pervades the animal creation, which gives a superiority of development to the right side. In some of the mollusk tribes you see this law prevail to such an extent that the right side is rolled round the left, as in the house snail. There is, on the other hand, in most healthy chests, an advantage on the left side in point of height. The apex of the left lung, and the corresponding portion of the chest, rises a trifle higher than that of the right. I cannot tell whether this is an original condition, or whether it results from the habitual inflated pressure of the stomach and the unyielding mass of the heart on the left side giving the chest a greater tendency to upward expansion, but the fact is pretty constant. Still these slight exceptions scarcely detract from the general symmetry of the chest, and when known can be allowed for. Where you find any considerable departure from this degree of symmetry, or correspondence between the two sides, you may be pretty sure that there either is, or has been, disease.

I have said that you may inspect the chest from *above*, as well as from before and behind. This may be done when the patient is sitting on a low seat, with his head a little bowed forward, by standing behind him and looking down on the shoulders. You thus get a view of the depth of the chest from front to back, and you may often detect a want of correspondence between the two sides, that is not perceptible by the ordinary modes of inspection.

If the patient's strength do not permit him to stand or sit up, you may inspect the chest when he is lying on his back; and this may be done not only standing by the side, but also at the foot and at the head of the bed, from which the corresponding motions of the two sides can be better seen.

Now the inspection of the chest is to be applied not only to its statical condi-

tion, but also to its motions; and here it is proper to employ feeling with it. Whilst, therefore, we are inspecting the chest, we desire the patient to breathe in various degrees; and with our hands and eyes on corresponding points of the two sides, we watch and feel the amount and equality of the motions. If the chest is a healthy one, we see the motions as uniform as the chest is symmetrical. The clavicle, scapula, and upper ribs rise; the lower ribs rise and spread; and the abdomen swells as the diaphragm descends at each inspiration. Attentively watching and feeling the chest will also often enable us to trace the limits of some of these movements, so as to indicate the boundaries of the chest. Thus we have before noticed that the lower ribs are pressed outwards, by the displacement of the abdominal viscera at each descent of the diaphragm, and constitute a fulness below the limits to which the lungs descend, with a slight flatness or hollow above. My friend, Dr. Edwin Harrison, has studied these marks so successfully, that he can discover in many cases, by simple inspection, the height of the diaphragm and liver. The intercostal spaces are also fit-marks for this mode of comparison between the two sides; and there are other useful details, which I cannot now enter into: they are soon learnt in practice, when the principle of the examination is properly understood. Applying the hand in the region of the heart, we feel the relation of the respiratory motions to that organ. After a full expiration the heart is felt beating close under the hand, about the cartilages of the fourth and fifth ribs, as well as under the sternum; but as the ribs rise, and the lung expands in inspiration, we gradually lose the beating, and if it is felt at all, it is now as low as the sixth rib. I shall not dwell longer on the healthy appearance and motions of the chest, but you should take every opportunity to study them; and you will then soon be able to scan them, just as a horse dealer judges by a few glances of the points of a horse.

We shall notice a few general varieties of respiration, which are to be determined by watching and feeling the motions of the chest. Healthy or perfect respiration is both diaphragmatic and costal; but under the influence of disease the motions may be confined either to the ribs only, or the diaphragm only. Thus, when the diaphragm is prevented from descending by acute pain in it or below it, or by pressure from below, the respiration is wholly performed by the raising of the ribs, and is called *heaving*, *thoracic*, or *costal* breathing. When the ribs, again, are immoveable, in consequence of pain, ossification of cartilages and ligaments, or paralysis of the

intercostal muscles, the breathing is wholly *diaphragmatic* or *abdominal*.

The movements of respiration may be *partial*, when one side of the chest is seen to move less than the other, or when a part of one side moves imperfectly; and this partial respiration may proceed from immobility of the parietes, or, as more usually, from impermeability of the corresponding portions of lung, in consequence of various diseases. Thus, when lymph or tubercular matter in the tissue of the lung, an obstruction of the bronchi, an effusion into, or a contracted adhesion of, the pleura, prevent the inflation and collapse of a part of the lung, the corresponding walls of the chest will be resisted in their motions, and will become fixed in proportion. Thus in phthisical patients we often see the ribs below the clavicles scarcely moving in respiration, and often sunk on one side; in pneumonia and pleurisy the lower ribs are more commonly fixed. Mark further how they are fixed, whether in a state of dilatation, or in one of collapse—whether the affected part remains full after expiration, or whether it is still sunk after inspiration, or whether it is fixed in an intermediate state: you may thus, in certain instances, go some way to distinguish between these different causes of pulmonary obstruction. But more of this by and by.

Examination by tact and vision requires, on the part of the observer, an exact eye, a good perception of shape and symmetry, or, if you will have it phrenologically, full organs of *size, form, and order*. It is often highly useful in the way of a general survey, preparatory to other more accurate modes of examination.

The plan of measuring the chest is a more exact method of detecting inequalities of size between the two sides of the chest. It is generally practised in this way: a piece of tape is fixed with one end on the spinous process of a dorsal vertebra, and carried horizontally to the middle of the sternum, first around one side, then around the other, in this way. [The method was shewn on a plaster figure.] Of course great care must be taken to pass the tape around corresponding parts; and attention must also be paid that the degrees of the respiratory act be the same during the measurement. The most accurate mode is to compare the measurements of the two sides on a full inspiration and a full expiration, as well as in the intermediate state. The process is rather a troublesome one, and we cannot, among private patients at least, use it often; but it sometimes gives results which are well worth this trouble.

Besides external measurement, which is essentially comparative between the two

sides, I may notice here a sort of attempt at internal measurement, by noting the quantity of air that can be *exhaled* or *inhaled*. Mr. Abernethy proposed to judge of the capacity, and consequently the soundness, of a man's lungs, by measuring how much air he could throw at a breath, after a full inspiration, into a jar inverted over water. Here is an apparatus which belongs to Dr. Green, of Great Marlborough Street: it measures the quantity of air taken in at a full inspiration. You see, when I close my nostrils and inspire through the tube, the water in the glass jar rises in proportion to the quantity of air which I draw in, and this is measured by the cubic inch scale on the side of the jar. There are other contrivances of a similar kind. The chief objection to them is that their indications are affected not only by the capacity of the lungs, but also by the strength of the respiratory efforts. They are *dynamometers* for the muscles of respiration, as well as *pulmometers*; and a weak, delicate, or nervous person, with sound lungs, tested by them, would be placed below a phthisical or pleuritic patient whose muscular energies are still considerable.

So much for *seeing* and *feeling*. They may often do something, but you will readily perceive that they will seldom inform us of the nature of the obstructions which they can discover, and they cannot discover many obstructions and disorders of a smaller degree. The chest may be immobile in parts, but whether from blocked-up air tubes, diseased lung, liquid or air in the pleura, or any other of the various causes, sight and touch will not inform us.

We are driven, then, to try another sense which may reach beyond the surface, —the sense of *HEARING*. Now this sense is not generally cultivated as our sense of vision is. "Seeing is believing;" to see a thing is almost the same as to understand it. The same can scarcely be said of hearing; but yet, in cases where we have exercised this sense, we by experience render its indications nearly as instructive as those of sight. Thus we know the different sounds of carriages and horses in the streets, the foot-steps of walkers, the sounds of rain falling, of wind whistling, and so forth; and these several noises are the acoustic signs of the nature or physical character of the various bodies that produce them. So also the acoustic properties of the chest and its organs, the sounds that are produced in them or elicited from them, may by study instruct us as to the nature and condition of the matter of which they are composed.

Now there are two methods of studying these phenomena:—1. By mere individual experience: just as the infant studies the

form and appearance of objects by sight and touch, and in time becomes acquainted with them. 2. Through a generalization of that experience in the laws according to which the phenomena occur. Personal experience is of course indispensably necessary to familiarize us with the character of the phenomena; but before it can inform us of their true nature and causes, experience must be extensive, and detailed to a degree that falls to the lot of very few; and even when thus obtained, its results, without generalization, must be so unwieldy and burdensome to the memory, that still fewer could duly profit by it.

We must avail ourselves of both methods. We must accustom our ears to the sounds in all their varieties, that we may be able by experience to know and distinguish them: but to understand their import, and to read the interpretation which they give of the condition of the parts that produces them, we must study them through the laws of which they are examples. We must consider what sound is; how it may be produced, transmitted, and modified; how the contents of the chest may produce it, and when produced can change it; and by comparing its general properties with the mechanism of the chest and its organs, we shall be prepared to understand and arrange the phenomena that experience has discovered, or may hereafter reveal to us. By thus learning the acoustic relations of the chest, not merely as isolated facts, but as parts of an applied science, we may be enabled to escape in great measure the errors into which unintelligible matters of memory might continually lead us, and we shall be acquiring a rational pathology instead of resting on an empirical diagnosis. In this study, as well as in many of the subsequent parts of the course, you will find my little work on the *Pathology and Diagnosis of Diseases of the Chest*, useful as a text-book; and supposing that to be in your hands, I shall dwell less fully on the matters which are contained in it. In fact, there is so much new matter to be brought before you, or at least so much new application and arrangement of that which is already known, that I shall often refer you to the best works for common details, and give our time chiefly to the development and application of principles which are not, or but imperfectly, to be studied elsewhere.

We must devote the next lecture to a subject purely physical, the nature and properties of Sound*.

LECTURES

ON

RHEUMATISM AND ITS EFFECTS;

BY R. MACLEOD, M.D.

Physician to St. George's Hospital.

Atmospheric vicissitudes the chief cause of Rheumatism—Effects of Hereditary Predisposition—Relative prevalence according to Sex and Age—Fibrous Tissues the Seat of Rheumatism; supposed continuity of these—Symptoms; pain the most general, but not universal Divisions of Rheumatism—Rheumatic Fever—Seat of the pain—The Inflammation not confined to the Ligaments—Absence of permanent organic change in the parts injured—Nature of the Constitutional Disturbance—Diagnosis between Rheumatic Fever and Gout.

RHEUMATISM, in common with other inflammatory affections, is held to be most rife during the winter; but this, although true in the main, is much less remarkable than with respect to most inflammatory diseases. Dr. Haygarth, who gave considerable attention to the subject, estimates the proportion of cases of rheumatism occurring in summer to those occurring in winter as five to seven; and I may add, that the attacks during warm weather are frequently quite as severe as those which take place at more inclement seasons of the year. In fact, it would appear that the cause of acute rheumatism is not to be sought for so much in any abstract degree of cold as in atmospheric vicissitudes; so that exposure to the cool air of an evening which follows a hot day is often sufficient to produce an attack of acute rheumatism, particularly if the atmosphere has become charged with moisture. Some, indeed, have supposed that other agents besides cold and moisture come into operation, and that malaria gives noxious energy to the influence of the air; but when we consider that rheumatism occurs under almost every variety of situation,—often, certainly, where there is no reason to suppose any malaria to exist,—and when we see it immediately following the application of cold and moisture, without the concurrence of any other apparent circumstance, it appears to me quite unnecessary to have recourse to other causes, the very existence of which is in many cases entirely hypothetical.

But it has further been supposed that, in order to produce rheumatism, some peculiar state of the individual—some constitutional predisposition—was required. In reference to this we may say, that whatever considerably reduces the general tone and

* Erratum in last lecture, p. 88, top of 2d column—for *intense*, read *inclement*.

vigour of the body, renders the individual more liable to rheumatism, but not apparently to a greater degree than with respect to other inflammatory attacks, the constitutional change being merely that of a diminished power of resisting disease in general—not rheumatism in particular. There are, however, two circumstances which enable us to know that one individual is more liable than another to rheumatism: the first is, his being descended of parents who have suffered from the disease, and the second is, when he himself has had it before.

With regard to the hereditary peculiarity which causes this proneness to rheumatism, although we may be at a loss to point out in what it consists, its existence, I think, admits not of doubt: indeed, it is stated by Chomel, as the result of specific investigation on this point, that of a large number of patients treated by him at La Charité for rheumatism, not less than one-half were the offspring of rheumatic parents.

Having suffered from rheumatism once, gives but too great a probability of suffering from it again; and it will rarely be found that an individual who has had rheumatic fever once, lives many years without experiencing its recurrence; so that many persons suffer from the acute form of rheumatism several times in the course of a few years,—while with respect to the chronic, we meet with some subjects in whom this disease in a greater or less degree is scarcely ever entirely absent. I know no certain indication of an individual having what may be called the rheumatic diathesis, except the disease having manifested itself; nor is it easy to conjecture in what that peculiarity in his organization consists which, in the first instance, gives to one man a greater liability than another to become affected with rheumatism. But after it has once displayed itself, it requires no great stretch of imagination to conceive such change to take place either in the physical condition or in the mode of action in the part attacked as shall leave behind it a permanent disposition to resume the rheumatic state,—just as we observe that one who has had cynanche tonsillaris, or almost any other inflammation, is more prone than before to have a recurrence of such disease.

Rheumatism in its acute forms is more prevalent among men than women; but I think the difference in this respect is not greater than the circumstance of the latter being less exposed to its exciting causes is sufficient to explain, without supposing any innate difference in the relative degrees of constitutional predisposition.

The early period of adult age is that at

which the greatest number of cases of rheumatic fever present themselves; and here also it is probable that the circumstances above alluded to,—I mean the greater exposure to the exciting causes,—may have some influence in producing the result. Probably two-thirds of the patients are between 15 and 30; but it is also met with in infancy, and I have repeatedly seen it in children of five or six years of age; while I have still oftener had patients with disease of the heart resulting from acute rheumatism, which had affected them in infancy. As we advance in life, the liability to the disease in the form of rheumatic fever diminishes; and it is comparatively rare after 50. There is, however, a considerable difference as to the frequency of different kinds of rheumatism at different periods of life; and the preceding remarks are to be regarded as most applicable to rheumatic fever, and least so to arthritic rheumatism, which more frequently attacks those beyond the middle period of life than the younger and more robust.

Rheumatism is a disease which has its chief, and some have even supposed its exclusive, seat in the white fibrous membranes; and there can be no doubt but that here, as in other cases, the organization of the part affected has great influence over the phenomena which result. The kind of tissue alluded to occupies a very large extent of surface in the human body: it nearly sheathes the limbs,—it constitutes ligaments which knit the joints together,—it forms sacs, which envelop the brain, the heart, and many of the glands,—it is gathered into the cords called tendons, and these are continuous with the periosteum or fibrous covering of the bones.

It seems to be a favourite conceit with anatomists, that certain textures in one part of the body are in some manner dependent for their formation on a similar texture in some other part; and in conformity with this idea they have endeavoured to trace some common source whence the fibrous tissues derive their origin. Bichat placed their common centre in the periosteum, while Clarus has more recently assumed it to reside in the membrane investing the muscles. Extended as is the “centre” adopted by each of these authorities, great difficulty is found in bringing all the fibrous tissues within the circle; for example, it requires no inconsiderable faith to believe that the sclerotic coat of the eye is but a prolongation of the dura mater, or that the tunica albuginea is but an expansion of certain fibres reaching the testes in the sheathing of its vessels.

But as it has long been an orthodox be-

lief, that inflammation spreads by continuity of surface, so it has been thought of importance to ascertain the route by which external diseases of inflammatory nature sometimes affect internal parts—as rheumatism, for example, attacks the heart. Now the pericardium has been supposed to maintain its connexion with the external parts either by means of the diaphragm, with which it is continuous at its apex, or through a prolongation of fascia covering the great vessels of the neck. This last idea has been especially dwelt upon by Dr. Godman, of Philadelphia*, who informs us, that “however singular it may appear that this arrangement should not have been discovered until this time, it is by no means as singular as that anatomists during so long a time should have remained contented to believe that a *serous* membrane like the pleura could form a strong *fibrous* membrane like the pericardium.” From these expressions it is evident that the learned professor is perfectly “contented to believe” that the bag which contains the heart is dependent for its formation upon the fascia superficialis of the neck. It is curious to observe a very intelligent physician in this country (Dr. Brown, of Sunderland) quoting this supposed connexion as tending to explain the frequency of the affection of the pericardium in rheumatism, although it be notorious to every practitioner who has attended to this disease that the throat, whence the disease is assumed to spread, is but rarely affected with it, while pericarditis is of very frequent occurrence simultaneously with rheumatism of distant parts, and where all idea of its having spread by continuity of surface is entirely out of the question.

But although this attempt to establish the existence of an unity among all the analogous membranes of the body be little more than a mere exercise of the fancy, it is very different when we come to investigate the peculiarities which mark those structures in particular parts, and which give character to their diseases.

Fibrous membranes are simple or compound. The former division includes *ligaments and fascia, aponeurosis, periosteum, and perichondrium*, varieties which differ in thickness and density, but possess the common properties of being fibrous, resistant, white, and more or less resplendent, insensible, having few vessels, and scarcely any nerves which can be demonstrated. Tendons and ligaments are made up of the same tissue, only modified by the arrangement of their fibres into bundles.

The compound fibrous membranes are those which are united with a different

tissue—as the serous, examples of which are presented by the pericardium, the dura mater, and tunica albuginea, and which are therefore called *fibro-serous* membranes. In the nostrils and mouth, the fibrous and mucous tissues are compounded; and in the air-passages and the ear we find an union with cartilage. In the form of inflammation, however, to which I wish more particularly to direct attention, the textures most frequently affected are the fibrous and fibro-serous, the aponeurotic expansions which cover the muscles, the periosteum, and the fibrous covering of the nerves. But the disease undergoes important modifications, according as one or other of these textures happens to be its seat: and in fact rheumatism presents itself under such a variety of different forms, that it is difficult or impossible to give any definition which shall convey an idea of the disease at once comprehensive and correct.

The symptom most general and most dwelt upon is pain; but this may be absent when the case is chronic, and the part at rest. Nay, rheumatic inflammation of the most acute nature may be present without the part affected being complained of, and this, too, though it be constantly in motion; for when the disease attacks the heart, it sometimes runs on to a fatal termination, without any pain having been referred to the chest. In one the disease is transient, in another persistent; in one it endures long, without giving rise to any organic change; in another it speedily produces such change of structure as proves rapidly fatal, or leads to protracted suffering, and more distant but not less certain destruction.

Without for the present taking into account the forms of rheumatism which affect the internal organs, and without including some of the rarer external varieties, we may enumerate the following as well marked, generally distinguishable from each other, and requiring considerable differences in their modes of treatment.

1. The patient may be attacked with pain in one or more joints, with tumefaction and redness, spreading to a greater or less extent over the surrounding parts. The swelling is here external to the joint, the hollows and protuberances about which are obscured, apparently by effusion into the cellular tissue. In this form the disease rapidly shifts its seat, and it is accompanied by acute inflammatory fever.

2. In another case the joints likewise are affected, but in a different manner from the preceding. The pain is more limited, and the swelling evidently depends upon effusion into the capsule, which is seen to bulge at those points where the surrounding ligaments present the least degree of resistance. The bursæ of the

* Anatomical Investigations: Philadelphia, 1824.

tendons are also frequently implicated, and become distended by an increased effusion of their lubricating fluid. In this form of the disease there is less redness, and usually less violent fever, than in the preceding. The great practical distinction between these two forms I believe to have been first made by Dr. Chambers: certainly others, who have not always remembered the original source of their information, were, like myself, first taught to make the distinction systematically, when following his practice at St. George's Hospital.

3. In a third the pain is chiefly referred to the parts intermediate between the joints, and seems to be seated in the muscles or their aponeurotic coverings. Here the pain, though it may be exquisite on the slightest movement, is not unfrequently entirely absent when the parts are quiescent: and here, too, there is often little or no constitutional disturbance.

4. In a fourth variety the disease affects the coverings of certain bones, especially those which are but slightly protected by integuments, such as the shin, the ulna, or the cranium: and under such circumstances there are often spots or patches more painful than the rest, tender to the touch, and elevated into nodes.

5. Lastly, the pain sometimes follows the course of particular nerves, more especially those of the lower extremities, and is occasionally confined to a narrow line, which the patient can trace with his finger. In such cases the power of motion of the limb is occasionally affected to a greater or less extent.

Now although all these be usually classed together under the general appellation of rheumatism, they are affections so different in their phenomena and treatment, that it is impossible for them to be understood either theoretically or practically, unless the distinctions alluded to be borne in mind; and without assuming that the textures specified are exclusively affected, or that the names are altogether free from objection, we shall proceed to speak of them as *Rheumatic Fever*, and the *Athritic*, or *Capular*, the *Muscular*, the *Periosteal*, and the *Neuralgic* forms of rheumatism.

Rheumatic Fever.

Rheumatic fever is a disease exceedingly prevalent among the class of persons admitted into the hospitals of this metropolis; indeed so true is this, that I am satisfied all medical men connected with those institutions will bear me out in the assertion that, if we take into consideration the ulterior effects of acute rheumatism, it is not only one of the most prevalent, but one of the most fatal maladies, incident to our precarious climate. If

this proposition should appear startling to any one, it can only be because he is not fully aware of the prodigious extent to which diseases of the heart, and dropsies, such as baffle all the efforts of our art, may be traced to an attack of acute rheumatism at some former period.

I know no cause which can be confidently pointed out as exciting this form of the disease, except atmospheric vicissitudes operating upon a frame predisposed to receive its influence.

The pain in acute cases is scarcely ever wholly absent, but it varies prodigiously in degree. It is always excited by the slightest movement of the affected parts, as well as by pressure, and is likewise greatly aggravated at night. This has been attributed to increased warmth, and in the chronic form of the disease with apparent justice, as the pain is frequently excited by heat applied during the day; but in acute rheumatism this explanation is insufficient to account for the circumstance; for, in the first place, when a patient is confined to bed, I do not perceive how he is to be warmer at night than during the day (so far as external sources of heat are concerned): and again, it is stated by Mr. Malcolmson, in his recent account of rheumatism in India, that the natives suffer an aggravation of pain at night, although placed under circumstances which render any increase of temperature from without impossible, as their repose is taken in any corner where they can find space to lie down, and without going to bed at all. A simple and more rational explanation of the increase which the rheumatic symptoms undergo at night is to be found in the nocturnal exacerbation which is experienced in this, in common with many other febrile diseases.

Acute rheumatism is generally ushered in by feverishness and wandering pains. These, for the most part, within a few hours, but occasionally not until the end of as many days, become localized. Sometimes one joint is especially attacked—sometimes several. Upon the whole, I think the most frequent order is for the foot and ankle, and then the knee, of one or both extremities, to be affected; next the hands and wrists, and after them, in point of frequency, the shoulders. The elbow is not so often the seat of attack as either the knees or shoulders; and the hip is implicated more rarely than any other of the large joints. It has been supposed that the relative frequency of attack depended upon the comparative degrees of exposure, and that those joints which are most covered suffer least. This explanation may serve to account for the hip-joint so often escaping, but it will not

explain why the elbow should suffer less than the shoulder. Such, however, has been the fact in a very large majority of the cases of acute rheumatism which have fallen under my observation.

The pain is often very severe, and the constitutional disturbance considerable, before the parts swell, or even where no tumefaction occurs at all. But in acute cases some swelling is usually perceived about the joints most complained of, within twenty-four hours. This increases, and the parts become tense; the hollows about the joints are more or less obliterated; the skin is hot, red, and sometimes shining; occasionally there is considerable swelling without redness; occasionally there is a blush of redness, or redness in patches, with little swelling, but generally the degree of tumefaction and redness bear a relation to each other. The part has very much the appearance of a phlegmonous inflammation, but one in which neither pointing nor fluctuation can be perceived.

One of the most remarkable characters of this inflammation is the rapidity with which it changes its seat in external parts. Generally in the course of a few days, and often within twenty-four hours or less, the pain diminishes, or wholly subsides, in the part first attacked, and simultaneously comes on in another; which then proceeds through changes analogous to those above described, to become released from suffering in its turn, while the inflammation either goes back to its original seat, or what is more common, invades some joint which had hitherto escaped. When the pain subsides the swelling does so too; but this always takes place subsequently, although often with great rapidity; so that within a few hours the part which was most tense may become perfectly flaccid, and have but a slight degree of soft cedematous fulness remaining. The skin in such cases becomes shrivelled and wrinkled, but after a time accommodates itself again to the subjacent parts, the cuticle very rarely desquamating, even where the swelling and cutaneous inflammation have appeared most intense.

It is astonishing how much the pain, as regards the limbs, is confined, in the majority of cases, to the joints above mentioned, and their immediate neighbourhood. In a certain number the loins, or the back of the neck, and the parts between the shoulders, become painful, but to a much less severe degree; and here the rheumatism, even when most severe, is usually unaccompanied by appreciable redness or tumefaction.

In all the parts above described as subject to acute rheumatism, there are *ligaments*; and it is probable that they, and the other white dense fibrous tissues, are

the primary seats of the disease. But it is clear that the inflammation is not absolutely confined to them; and indeed we see it in the skin, which is often so red, and with so much effusion beneath it, that it is by experience alone we become aware that suppuration is not impending. It is astonishing how little permanent change remains about the joint, even after repeated attacks, in which respect there is a great difference between this and the synovial, capsular, or arthritic form of rheumatism. Indeed, under ordinary circumstances, no injury whatever is done to the joint in rheumatic fever. Some degree of stiffness may remain for a time; but this seldom fails to wear off very speedily, when the parts to all appearance become perfectly restored. Perhaps about the back of the hand and dorsum of the foot more frequently than elsewhere, a slight degree of thickening may remain, a certain portion of the lymph which was effused having there become organized.

Opportunities very rarely present themselves of examining the joints during the actual existence of acute rheumatism, because patients very seldom die during a first attack; I have, however, in two instances, been able to examine the state of the parts primarily affected, owing to the disease having proved fatal by extending to the heart, but without finding any very striking result. The external redness had disappeared in both cases, and the swelling was very much diminished, so that nothing appeared but a certain portion of serum, or serum and lymph, in the subcutaneous cellular membrane. The ligamentous tissues appeared *perhaps* rather thicker than natural, but without redness; the synovial membrane without any apparent participation in the disease.

In a case of rheumatic fever which recently occurred to M. Chomel, of the Hôtel Dieu, Paris, the patient was rapidly cut off by pericarditis. As there had been severe affection of the joints, with much swelling, during life, Chomel examined them carefully after death, and describing the result he says—*l'examen de toutes les articulations n'a fait découvrir dans aucune d'elles le plus léger vestige d'un travail inflammatoire.*"

The circumstances here are altogether considerably different from those attending the form of rheumatism which I shall next have to describe, and in which the internal structure of the joint is often conspicuously changed. In fact it would appear that, in the form of the disease we are now considering, although the inflammation frequently extends both to the integuments and to the deeper seated structures, yet that it is a kind of inflammatory action but little prone to disorganize

zation; and I believe it is only in cases where the synovial membrane is affected that any permanent injury is done to the articulation, however active the rheumatism may be while it endures.

Besides the parts above enumerated, there are some others which are occasionally affected—probably in their fibrous textures—namely, the scalp, and the parietes of the chest and abdomen. I have placed them in the order of frequency in which they have fallen under my own observation, but without pretending to say that it holds good universally. The affection of none of those parts, however, can be looked upon as conspicuously or peculiarly belonging to *acute* rheumatism, which, in a very large proportion of cases, is entirely confined to the extremities; or if any other part be implicated, it is usually the loins, back, or neck.

When the scalp is affected, it is sometimes tender at different points, so that the slightest pressure causes acute pain; and in a few instances there is slight but perceptible redness, and puffiness of the integuments. In one case which I treated a few years ago, the bridge of the nose became swollen, red, and tender, simultaneously with rheumatism elsewhere, and subsided when this was subdued. Upon the whole, however, the affection of the scalp is much more common in certain chronic forms of the disease, which I shall have to consider hereafter.

The most common form in which rheumatism presents itself about the parietes of the chest, is as a "stitch," generally in the intercostal spaces, and low down on either side, though it may occur at any part of the thorax. Rheumatism in this situation interferes with respiration, the act of raising the ribs causing very acute pain. This kind of rheumatism may therefore be mistaken for pleurisy; but is for the most part readily distinguished by the external tenderness. The least touch is acutely felt in rheumatism, whereas, to increase the pain by pressure in pleurisy, it must be made between the ribs, and pretty firmly. It is also to be distinguished by the partial or complete freedom from suffering when the ribs are fixed, and respiration is carried on by means of the diaphragm—by the circumstance of cough being absent, or at least not necessarily present, in rheumatism, whereas in pleurisy it is rarely wanting—by the degree of constitutional disturbance being much less than in pleurisy, if the rheumatism be confined to the parietes of the chest, while its appearance elsewhere, if it be not so confined, renders any other diagnostic mark almost superfluous.

I have sometimes supposed that the diaphragm was the seat of rheumatism,

from the manner in which the pain darted through from the sternum and edges of the ribs to the back and loins; nor is there any difficulty in believing that this may be the case. Such occurrence, however, is evidently rare, and is rather matter of curiosity than of practical importance, because even if we were pretty well assured of its presence, we could not prudently adopt any other treatment than that adapted to inflammation from any other cause.

Rheumatism of the abdominal muscles in an acute form is principally met with where some peculiar circumstance has led to their unusual exposure to cold. Thus I have seen several instances in which persons riding or driving, with a cold wind, or wind and rain, beating in their face, have suddenly been seized with acute pain across the abdomen; generally, though not always, with rheumatism elsewhere. This pain is greatly aggravated when the abdomen is protruded in inspiration, or by attempting to bring the body into the completely erect posture, and is almost or entirely prevented by tying any thing rather lightly round the belly, so as to limit the action of the muscles. It can scarcely be looked upon as one of the forms of rheumatic fever,—at least, I have never seen it attended with redness or tumefaction, nor with constitutional disturbance, unless there was also rheumatism elsewhere.

I think I have seen rheumatism of the tunica albuginea testis. A gentleman, subject to rheumatism, complained of acute pain in one testicle, coming on suddenly, accompanied by increased heat and by great tenderness to the touch, but without tumefaction; and this again shifting from one testis to the other, and at last disappearing as suddenly as it had come on—just in the manner we see rheumatism change from one joint to another.

The constitutional disturbance which attends acute rheumatism is of a well-marked and striking character. When any of the dense ligamentous structures are in a state of active inflammation, the general system sympathises largely with the suffering part; in fact, it would appear that the less vascular and more insensible the texture, the more ardent is the fever which is lighted up when it has become inflamed. So in the ligamentous form of rheumatism, we meet with as violent specimens of reaction as we are ever called upon to witness. The chilliness or shivering with which this, in common with other acute fevers, is ushered in, having passed away, becomes speedily followed by great heat of skin, with copious but partial perspirations, which are almost invariably acid, rapidly reddening litmus pa-

per, and frequently exceedingly sour to the smell. The pulse increases to 90, 100, or 110, in frequency, and has a peculiar character. In books it is usually stated rather emphatically not to be hard; but I do not think this quite correct. The pulse is large, full, and active; not so hard as the small, concentrated, incompressible pulse of serous inflammation, but often quite as hard as a pulse of such size can well be supposed to become. The heat of skin and activity of the pulse bear a relation to each other, as might be expected; and sometimes both are less exalted than I have above supposed, the heat being moderate and the pulse large, but soft. Such cases usually yield to treatment more speedily than the others.

The tongue, where the fever runs high, becomes deeply loaded, white, and clammy, or even yellowish and dry. No acute disease, except continued fever, exhibits so thick a fur, and the coating of the tongue is even more uniformly present in acute rheumatism than in the common fevers of this country. The appetite is impaired, but generally not so absolutely annihilated as in fevers proper; there is also much less urgency of thirst. The bowels are sluggish and loaded, the evacuations dark and offensive. The urine scanty, generally much, and sometimes prodigiously, loaded with the lithates.

A remarkable difference between this and other forms of fever approaching to it in violence, is the comparative infrequency of what are called nervous symptoms. Delirium is a very rare occurrence; indeed I have never seen it, so long as the rheumatic inflammation has been limited to the external parts, and in many very acute cases there is no headache from first to last.

How long a case of this kind of medium severity might endure if left to itself, I am unable to say; but, with the common methods of treatment, probably five or six weeks may be about the average duration of rheumatic fever. Sir Charles Seudamore says, that "in a case of which the issue is favourable, the fever and pains are brought to a close at the end of the third week, and in slight attacks at an earlier period; but when the course of the disease is untoward, a period of two months scarcely serves to exhaust its power in producing even acute symptoms." This, indeed, is, I believe, in accordance with the generally received opinion, which has led to rheumatic fever being looked upon as in some sort like the eruptive fevers; having a more or less definite course to run, and through which it was the business of the practitioner to endeavour to guide his patient safely, rather than to arrest the disease by any very active interference. So far as I am able to judge, this opinion is not well founded;

and a more correct pathology would induce us rather to class rheumatism among the active inflammations, and one which, like them, may often be speedily extinguished if met at the onset by appropriate means.

When the disease is at its height, it is difficult to imagine a more complete specimen of helpless suffering than the patient presents: he lies motionless as if cased in mail—deprived of that temporary relief which change of posture often affords in ordinary fever. Absolute rest, indeed, seems to mitigate the suffering to a certain extent; the slightest movement of the limbs, whether by a voluntary effort or even the passive motion effected by an attendant, exciting acute pain. But it is only during the day that quiescence brings this partial respite, for towards night the pain becomes aggravated, and continues so till morning. The fever observes corresponding changes, but not, I think, to the same extent as the pain. The exacerbation both of the local and general symptoms appears to me, however, as I have stated, to be only in accordance with that general law of diurnal revolution which we meet with in so many diseases, and not to be dependent on the accidental, and indeed often imaginary, cause assigned for it in the increased warmth of bed.

As the disease is overcome by treatment or the spontaneous changes in the system, all the symptoms progressively, and sometimes very suddenly, abate—the pain first, and then the fever, or rather, perhaps, they subside simultaneously; but I seldom can observe any thing *critical*, in the ordinary acceptance of that term. It is true that the perspiration loses its sourness, and the urine drops its sediment; but when this occurs the pain and swelling of the joints will be found already to have subsided, so that we need not look for other proofs of the disease being already on the decline.

Persons who suffer from rheumatic fever are subject to relapse, especially from stimulating treatment or premature exposure; but with these exceptions the recovery is generally complete where the heart has escaped injury; and so far as my experience goes, such individual is scarcely, if at all, more liable than any other to have the disease in a *chronic* form. There is, however, a subdued form of rheumatism which often follows an acute attack, and which, in reality, is this form of the disease in a mitigated degree. There is pain about the joints which have previously suffered more severely, and which, on but slight exposure to cold, becomes attended with swelling and some degree of fever. In this it differs from the chronic form, which is situated more about the

muscles intermediate between the joints, unattended with any perceptible swelling, and, unless during a severe nocturnal exacerbation, unaccompanied by fever.

I know of no disease with which rheumatic fever can well be confounded, except an attack of gout, or of the capsular form of rheumatism.

The distinction between acute rheumatism and gout may be drawn either from the general or local symptoms; and when they are viewed collectively there cannot, under ordinary circumstances, be the slightest difficulty in drawing our diagnosis. Rheumatism so acute as to incur the risk of being confounded with gout, is almost invariably the obvious result of exposure to cold, and may attack a person previously in perfect health. Gout rarely makes its invasion without premonitory symptoms; as a general rule, it is preceded and accompanied by derangement of stomach, and accordingly, in at least nineteen cases out of twenty, more or less loss of appetite, nausea, acidity, and flatulence, usher in the paroxysm. In rheumatism, as we have seen, the bowels are generally torpid and the evacuations unhealthy, but the stomach does not suffer more than in any other form of inflammatory fever. The fever in gout has a much more marked remission, and bears a more obvious relation to the intensity of the local affection. The period of the first invasion in gout is almost invariably at night; whereas rheumatism may come on at any time. Gout is locally much more partial to particular joints—as, in the first instance, to that of the great toe; and it seldom affects many joints at a time. The swelling is not so diffused as in the acute form of rheumatism, but may be perceived, as it were, to proceed from within the joint, the synovial membrane of which is distended; and when it spreads to the integuments, which it does very rapidly, they assume a deep fiery red, with shining tenseness, and pit on pressure. Lastly, as the fit subsides, the skin itches and the cuticle desquamates: phenomena which scarcely ever occur in rheumatism, however acute.

The character of the suffering, too, is different; but this mark has the disadvantage of being dependent on the description of the patient. In gout the pain is of a gnawing, throbbing, and burning kind, with a peculiar sense of weight. In rheumatism it is acute and lancinating on the slightest motion, and sufficiently difficult to bear, but, unless when the patient moves, it does not equal the torture of acute gout. In rheumatic fever, much of the habitual distress, when the patient is at rest, depends upon the pain being so extensive; in gout it rather depends upon its being so intense.

In rheumatism fever often precedes the local inflammation; in gout, the symptoms which precede the attack are rather of the nervous kind, and the fever follows, or at least is only contemporaneous with, the articular affection. In rheumatism the first attack is usually the most severe as regards the external parts, and the subsequent invasions frequently diminish; at least there is no tendency on their part to increase in severity. In gout, just the reverse is the case; and that often in a marked degree.

The diagnosis between rheumatic fever and acute capsular rheumatism, will be best considered in speaking of the latter.

TREATMENT OF FRACTURES.

To the Editor of the Medical Gazette.

SIR,

IN the year 1833 I published an account of an apparatus for the treatment of fractures, and more especially compound fractures of the lower extremities, which, as I believed, possessed many important advantages over other contrivances for the same purpose. Since that time I have had numerous opportunities of putting to the test the real value of the instrument, and have had ample reason to be well satisfied with the results.

The instrument, which may properly be called a fracture-bed, from the perfect repose which it secures to the fractured limb, is possessed of the following peculiar advantages:—

1. The leg is supported in an easy sling, which admits of being adjusted in the nicest manner as to the actual or relative heights of the knee and foot, in accordance with the feelings of the patient or the views of the surgeon.

2. The reduction of the fractured bones, and their maintenance in the natural position; from which, with a little attention, there can be no hazard of deviation. These indications are effected by means of a screw, acting in the gentlest but most powerful manner upon the foot in fractures of the leg, and the knee in fractures of the thigh, giving the patient but little pain at the time of reduction, and none when that intention has been properly accomplished.

3. In cases of compound fracture of the leg, when the wound is large, and the discharge considerable, the dressings and bandages may be replaced, and the wound perfectly cleansed, without any

interference with the position of the limb, and with scarcely any uneasiness; certainly not more than would attend the dressing of a wound of equal magnitude and sensibility, unconnected with a fractured bone.

4. In consequence of the sling in which the leg is suspended, the patient is enabled, without hazard of displacement, to move the pelvis to a certain extent for the purpose of relieving the irksomeness of a long-continued unvarying position, or while using the bed-pan.

5. In fractures of the upper portion of the thigh, near the great trochanter, or of the neck of the femur, whether external to, or within the capsular ligament, a very perfect degree of coaptation may be secured, so as to preclude any shortening of the limb or permanent lameness. This is effected by the action of the screw on the back part of the fracture bed, until it is made to reach from the ham to the tuberosity of the ischium, while the external part is extended in a similar manner to the upper extremity of the femur, the pelvis having been fixed by a strap passed between the legs, so as to embrace the ramus ischii and pubis, and attached to the iron loop at the upper end of the instrument. In some cases greater security may be obtained by a second strap passed round the pelvis.

To detail the cases which have proved to me, in the most satisfactory manner, that these advantages are really to be obtained by means of this fracture bed, would prolong this communication beyond my present intention, but they have been witnessed and acknowledged by many intelligent surgeons; and I may add, that, in passing through this place a few weeks ago, Sir Astley Cooper had an opportunity, when inspecting our Infirmary, of witnessing its use in a case of compound fracture of the leg, of a very bad description, when he expressed his approbation of its operation. In several cases of this kind, attended with extensive lacerated wounds, and wherein exfoliation must necessarily ensue in the course of recovery, in consequence of the bone being for some extent denuded of periosteum, cures have been effected, without deformity or shortening of the limbs, which, I apprehend, could scarcely have been accomplished without the assistance of such an instrument; and the degree of ease and freedom from anxiety with

which the treatment has been conducted, is well worthy of being taken into account. A severe case of this character is at present far advanced towards recovery in this Infirmary, in which the original wound was not less than six inches in extent, and the bone, denuded of periosteum, was very considerably protruded.

Since I formerly requested the attention of surgeons to the facilities afforded by this instrument, I have made several alterations in its construction, which have had the double advantage of improving and simplifying its application, and materially diminishing its cost. These I shall endeavour shortly to explain.

1. Wood, with brass screws and mountings, has been substituted for iron in the construction of the instrument.

2. The paddings have been dispensed with, and their place is supplied by a small pillow, reaching from the ischium to the bend of the knee.

3. The bag for supporting the leg, with its numerous straps, and the studs to which they were suspended, has also been dispensed with; and, in dressing, its place is advantageously supplied by about four strips of bandages, passed in succession from one of the parallel bars, which extend from the knee to the foot-piece, under the leg, and tied at the opposite side, so as to give the most comfortable support to this part of the limb. A small narrow pillow may be interposed between these strips of bandage and the leg; but this is not essential. When the wound, in cases of compound fracture, is dressed, strips of bandage are passed round it in succession, so as to answer the purpose of a many-tailed bandage, before the suspensory strips, already alluded to, are passed from one parallel bar to the other, in the way described above. All this is done with the greatest ease, and in a very short space of time.

4. The key, which was formerly used in extending the foot-piece, is no longer needed. This action is now effected by means of a female screw, which moves on the cross bar, through which the screw of the foot-piece passes. In the thigh-piece the same object is effected, by means of small moveable bolts in the manner of the bolt which moves the screw of a vice.

5. A nicely-constructed hinge renders the knee of the instrument flexible,

the degree of flexion being determined by the height to which the sling is raised, which admits of perfect regulation in conformity with the wishes of the surgeon.

6. The support for the sling is made to resemble the frame-work of a stool inverted, the supporting leather straps being fixed to the extremity of each leg, either by means of a screw or a kind of buckle, well adapted for raising or depressing the sling, either at the knee or foot, as circumstances may require.

The difficulty of conveying in words what a glance at the instrument would enable the observer to comprehend almost in an instant, will, I fear, render this description not very distinct; and I can scarcely hope that drawings, to illustrate my meaning, would be admitted into your pages. Should I be incorrect in this supposition I shall gladly furnish you with sketches which will make the descriptions easily understood; and, desirous as I am of having the instrument tried by other practitioners, from a conviction of its practical utility, it will give me pleasure to supply any information which I have failed to introduce into this communication.

I may add, that the instrument, in its improved form, has been well constructed by Mr. Brown, an instrument maker of this place, on terms which place it more within reach for practical purposes.—I am, sir,

Your obedient servant,

T. M. GREENHOW.

Newcastle-upon-Tyne.

October 9th, 1837.

[Any drawing which can be represented by a wood engraving, we shall be happy to receive.—Ed. Gaz.]

ON THE INDUCTION OF PREMATURE LABOUR.

To the Editor of the Medical Gazette.

SIR,

If the following case possess sufficient interest to be worthy of introduction into your useful and scientific journal, you will, by its insertion, oblige

Your obedient servant,

EDWARD AUGUSTUS CORY,
Surgeon to the East London
Lying-in Institution, &c.

Cannon Street Road,
St. George's in the East, Oct. 16, 1837.

Mrs. H., of short stature, and aged about 30, had twice undergone the operation of embryotomy. I attended her, for the first time, about three years since, when the same operation was again deemed necessary, and was performed in the presence of a most respectable practitioner. The pelvic deformity was of the reniform character, the space between the sacro-vertebral angle and symphysis pubis (conjugate diameter,) being about two inches and three-fourths. It was consequently determined, should the recurrence of pregnancy render it necessary, that the premature induction of parturition, at the seventh month of utero-gestation, should be had recourse to, as affording the only means of saving the infant from the murderous application of the perforator. She had again become pregnant, and it was calculated that she had arrived at the seventh month of her pregnancy, about Thursday, the 14th of September last. From some remarks and cases which have been recently published by Dr. F. Ramsbotham, it appears that he has succeeded in effecting the induction of premature labour, "*solum ope secalis cornuti*." I was, therefore, led to employ this substance according to the formula he has suggested, viz.

R Secal. Cornuti ʒij.; Aq. Bullient.
ʒviij. infunde per semihoram, et addo
Acid. Sulph. Dil. ʒij. Syr. Simple.
ʒij. Tr. Card. Co. ʒij., ut ft. Mist.
cujus cap. cochl. ij. mag. q. quartā
horā.

The first dose of this mixture was ordered at 2 p. m., on the 14th of September. At 6 p. m., soon after the administration of the second dose, the uterine energy became slightly excited; and it was interesting, as well as satisfactory, to observe its gradual increase soon after the repetition of each dose of the medicine. On the next day (Friday) at 1 p. m., the parturient pains were tolerably active, but at considerable intervals. A vaginal examination was instituted, and the membranes were distinctly felt pressing against the dilated os uteri. Saturday, at 11 a. m. the pains had gradually diminished in force and frequency since my last visit, and she had experienced no pain from yesterday at 4 o'clock p. m. to the present time, and was, to use her own expression, "quite well again." The institution of another vaginal ex-

amination- demonstrated that the os uteri had not, in the least degree, increased in dilatation, and that the pressure of the membranes which had been previously experienced, even during the interval of pain, had now entirely subsided. She expressed great anxiety and apprehension as to the result.

On the same day, about 6 p.m., I again visited her, and found her precisely in the same situation. I was fearful of repeating the *secale cornutum*, lest it might destroy the infant. I therefore thought it most prudent to rupture the membranes, the distension of which had now completely subsided; and this, having converted the nail of the index finger into a saw, I accomplished with some little trouble.

She was again visited on Sunday, at a little after 1 p.m. She remained in a similar condition, and there had been no accession of the pains of parturition.

On Monday she had not yet experienced any pain, and the bowels being in a constipated state, I thought it prudent to prescribe an aloetic purgative, with a carminative addition, which had the effect of thoroughly evacuating the bowels, and exciting the uterus to action; so that early on Tuesday morning the pains of labour commenced with considerable activity, and continued with but slight intermission until six o'clock in the evening, when she was delivered of a living infant of healthy appearance. The foetal head, notwithstanding the severity of the parturient paroxysms, occupied several hours in its passage through the contracted pelvis, and, after expulsion, presented on its lateral portion an evident indentation, and was also considerably flattened. The whole process terminated as in a common accouchement. The placenta was expelled, with but little assistance, about half an hour after the birth of the infant, which was restored in ten minutes by immersion in the warm bath, and by artificial respiration. The child remains at the present time (Oct. 16) healthy and vigorous, takes the breast freely, and there is every probability that it will continue to live. The patient has not suffered the least pain or inconvenience since her delivery; in short, I never witnessed a more rapid recovery even in an ordinary case.

REMARKS.—The necessity for the induction of premature labour in the present instance must, I think, be evident to every well-informed obstetrician; and I also am of humble opinion, that the means so carefully adopted for the production of so desirable an object were based upon the soundest principles of obstetrical science. I am induced to believe, that had I continued the administration of the *secale cornutum* for a longer period, that the expulsion of the infant might most probably have been effected without the necessity of the least manual interference; but I was deterred from persevering in its use from the apprehension that it might exert a deleterious effect upon the infant, and also injure the mother. I was fully aware of the great importance of maintaining the membranes entire as long as possible, in order to be able with greater certainty to insure the safety of the infant; but as the *secale* failed to produce the anticipated result, I was reduced to the alternative of rupturing the membranes, even with some risk to the infant, rather than hazard, perhaps, irretrievable injury both to the mother and child, by persevering in the administration of the *ergot*. The induction of premature labour appears to have been practised by the ancient physicians, more particularly by *Ætius* and *Paulus Egineta*, who recommended it in cases of extreme contraction of the pelvis; but it was not until about the middle of the last century that the most eminent practitioners in London decided on its propriety and morality. It may be laid down as an incontrovertible obstetrical axiom, that if there be less than the space of three inches, and more than two and a half, between the sacral promontory and the pubes, that the induction of parturition at the seventh month of utero-gestation becomes indispensably necessary, and its utility will be rendered more evident when we consider the disproportion between a structure thus constituted, and the foetal head at the full period of intra-uterine maturity. From accurate and multiplied observations, *Madame Lachapelle* has arrived at the conclusion that the biparietal diameter of the foetal head at the seventh month of pregnancy does not measure more than three inches, and sometimes even less; and, therefore, allowing for its compressibility in

consequence of incomplete ossification, it may be easily imagined that no very considerable difficulty will be experienced in its passage through such a pelvis as I have mentioned. The records of the science prove most satisfactorily that the woman is not subjected to greater risk by premature labour induced artificially, when carefully performed, than by spontaneous parturition at the full period of gestation. The existence of some morbid affection, rupture of the uterus, or some accident entirely independent of premature delivery, has been invariably discovered in those cases which have had a fatal termination. Denman operated eight times with complete success (*Introd. to Midwifery*, vol. ii. p. 224). M. Salomon mentions sixty-seven, Kluge twelve, and Ferrario six, which also terminated successfully (*Journal Compl. des Sc. Méd.* §c. tome xxxiv. p. 339). In the practice of Reisinger (*Dict. de Méd.* 2d edit. tome i. p. 429), one died in fourteen; but Merriman (*Synopsis of Difficult Parturition*, §c. p. 161) has not lost one in forty-six upon whom he appears to have operated.

Artificial premature delivery does not, however, terminate so happily with regard to the infant. In forty-seven cases which occurred in the practice of Merriman (*Synopsis*, §c. p. 180), twenty-six were dead, five were born living, but not possessed of viability, and sixteen lived. Hamilton has been more fortunate, and in twenty-seven cases has succeeded in preserving the lives of twenty-three (*Ryan's Manual*); Ferrario, five in six; Kluge, nine in twelve; Salomon, thirty-four in sixty-seven; and Burekhard (*Thesis, Strasburg*, July 20, 1830), thirty-five in fifty-two. Premature delivery has also been recommended in cases entirely unconnected with pelvic distortion. Its performance has been proposed by Mai, Ritgen, and Carus, in those instances where the fetus habitually dies some time before the expiration of the full period of gestation, as well as in some diseases induced by pregnancy, which are dangerous to the mother, as metrorrhagies, retroversion, &c. Siebold, according to Kilian (*Die Operative Geburtshilfe*, vol. i. p. 380), practises it in ascites and hydrothorax, and M. Costa (*Revue Médicale*, 1827, tome i. p. 343), thinks it necessary in diseases of the heart. Conquest (*Outlines of Mid-*

wifery), Ingleby in his work on Uterine Hæmorrhage, Busch (*Lehrbuch der Geburtskunde*, 2d edit., 1833), and other authorities, have also recommended it in cases entirely independent of pelvic distortion. My limits will not permit me to discuss the propriety of its adoption in the various morbid conditions just alluded to, but it is evidently the only rational means of relieving the woman who has the misfortune to be affected with diminution of the natural dimensions of the pelvis, and of rescuing her infant from inevitable destruction.

The operative methods which have been proposed and practised for the induction of premature labour are very numerous, but the one most usually had recourse to, and upon which the greatest reliance can be placed, is the sudden evacuation of the liquor amnii, either manually or instrumentally. Some writers of celebrity have advised its gradual discharge, but the majority have decided in favour of the former, as by the sudden vacuity of the uterus that organ is more likely to take on a brisk parturient action, by which means there will be a greater probability of saving the life of the infant. I consider, also, that there can be no objection to the previous administration of the ergot, according to the formula, and on the respectable authority, of Dr. Ramsbotham; and in some cases I am inclined to believe it may (*per se*) produce the desired effect. I may add, in conclusion, another mode of procedure, which appears to be in high repute with the practitioners of the French school, although I cannot recommend it on my own personal experience. Velpéau (*Traité Complet de Part des Accouchemens*, tome ii. p. 413), thus mentions it. "La dilatation au moyen d'un morceau d'éponge, comme la imaginé M. Kluge, est d'un effet beaucoup plus certain. L'irritation qu'en résulte est permanente, progressive, régulière, et soutenue par la pression qu'exerce l'espèce de tampon qu'on maintient en même temps dans le vagin. Sous l'influence d'une pareille excitation, la matrice entre bientôt en action, et il est difficile que le travail n'acquière pas rapidement une énergie suffisante."

ON THE EDUCATION OF GENERAL PRACTITIONERS.

To the Editor of the Medical Gazette.

SIR,

IN my letter of the 7th of August, inserted in your number for the 19th, I offered some suggestions, by which, as it appeared to me, a more equal and certain acquisition of knowledge would be attainable by students, without any increase of expense.

I took a sketch of the wants of the public in medical and surgical affairs, on ordinary occasions, ventured to make a comparison between the condition of gentlemen educated to the other learned professions and "general practitioners," and submitted for consideration whether a high standard of qualification, based on an expensive education, might not lead to disappointment, tend to abridge occupation, and eventually become injurious to the public and the profession. Two gentlemen have noticed my remarks, Mr. Meade and Mr. Norton. The former thinks that my plan "of exacting a more regular attendance upon lectures" seems "only likely to aggravate, rather than relieve the evil." Now I must confess it is paradoxical, that the evil, viz. defective knowledge, should be increased, or aggravated, by a steady and systematic, instead of an uncertain and irregular, attendance at the sources of elementary instruction, unless Mr. Meade could shew that all pupils who had so absented themselves would have actually employed their time, during absence, more advantageously. Mr. Meade then jocosely observes, "I do not know whether Dr. Kerrison could devise a plan by which it might be known, whether men listened to, as well as were present at, the lectures." To this I reply, that I can neither confer intellect, nor command attention; but that I have sufficient confidence in the good sense of medical students to believe that they could understand the lecturer, and that they would *not* be so wilfully perverse as to disregard the subject of the lecture; therefore I see no reason to doubt that they will become better acquainted with the respective departments of science, when their attendance shall have been made imperative, instead of remaining optional.

The other part of Mr. Meade's communication is no answer to my letter; it merely decries apprenticeships, and extols the system of private teaching by junior lecturers.

With respect to apprenticeship, Mr. Houlton's letter, in the *GAZETTE* of the 9th of last month, presents so forcible and just an appeal to the understanding, that I am inclined to think Mr. Meade had not been fully aware of the manner in which it can be made useful in training the mind of a youth to the details of his future professional duties, as an apothecary, or a "general practitioner."

As to the other point, I am not disposed to deny the advantage of a double system of teaching, where pupils can afford to pay for it; but it has been often remarked, that the expense of a medical education is already great; and it appears to me more consistent with the dictates of reason to ascertain what improvement can be effected by a more regular attendance at the public classes, than to connive at, or even to permit, the present negligent mode to prevail, and to force young men upon the system of *grinding* and *cramping*, in order to get up a technical smattering, for the purpose of passing their examinations.

I know that much diversity of opinion exists respecting medical education, and that some think a "general practitioner" ought to be a profound anatomist, and an expert operator—capable of demonstrating the minutest parts of the body, of crushing a stone in the bladder, or of extracting a cataract, besides being equal in medical affairs to the most able physician.

Mr. Norton has commented on a detached part of my observations. He thinks "that the education of a general practitioner should be of the highest stamp, as he is in most cases the first called in, and is *expected* to be able to treat, competently, every case."

I will not attempt to deny that practitioners of the highest stamp are best able to fulfil the expectations of the public; for I have already stated that there are many gentlemen engaged in pharmacy possessing very high qualifications; but I have endeavoured to distinguish between that which seemed practicable, as to the general rule, and that which was possible, as the exception. Let us, then, take a review of professional education as it now exists,

and has existed during the last twenty-two years, or since the Apothecaries' Act came into operation, and as it used to be pursued by the respectable class of pupils long before that time*. Let us look steadily at its results, and then acknowledge frankly whether such expectations can or cannot be realised.

A few young men commence their scientific and hospital studies, who are sons of gentlemen in practice; their preliminary education has been good, and they are well prepared to imbibe knowledge: a few others have been, or still are, apprenticed to general practitioners in London, who are not indifferent to the advancement of their pupils, and permit them to proceed with this part of their education during the latter years of their apprenticeship, in the manner explained by Mr. Houlton. These two classes are not numerous; their peculiar condition leads to the expectation under ordinary diligence of high attainments.

The great majority of students, however, arrive in the metropolis from provincial districts, where no lectures had been given, or they have been apprenticed in London to masters less able, or less willing, to allow them to attend lectures and an hospital; or, at most, may have permitted a partial attendance, under limitations which nearly destroyed all beneficial result.

Such young men constitute, probably, eight or nine-tenths of the whole number of students; they come to London for a limited period (called walking the hospitals), and are often undecided to what medical school they shall attach themselves. In this age of extraordinary competition of teachers, they are not always fortunate in their choice. Those who are not resident with parents, relatives, or masters, get into lodgings in the neighbourhood of their lectures, or board in a family, during the few months of their sojourn in the

metropolis: their pecuniary means are often slender, and no extension of time is in general allowed beyond that which is absolutely necessary to complete the course of study (called curriculum), to qualify them as candidates for examination at the Royal College of Surgeons, and at Apothecaries' Hall.

Several hundred young men, thus annually thrown upon a sort of college life, with few restraints and no regular superintendence, meet in the classrooms, and soon form associations and acquaintance with each other. Assuming that they all possess good principles, they are nevertheless of various dispositions, and may be subdivided into two general classes—the industrious and the idle—with all gradations of both.

The industrious learn as much as they can, scramble through their every-day duties as well as they may, and in their meritorious endeavours to excel, often become indisposed by attempting to do too much, and by having led a sedentary life in the atmosphere of a crowded part of the town and a dissecting-room. Many young men of this class, particularly those from the country, are compelled to pause, and sometimes to return home to recruit their health, before the medical session (from October to June or July) has expired; and they lose, in this manner, part of their proposed education in the first year.

They return to London in the autumn, to complete the curriculum of study in new subjects, having an imperfect acquaintance with those which they had been forced to abandon; and these industrious students incurred the danger of being rejected at their examinations, unless an extension of time had been obtained to enable them to proceed with greater certainty of success. In the autumn of 1835, the period of attendance at lectures and an hospital, to qualify a candidate for examination at Apothecaries' Hall, was extended to three winters and two summers*.

In addition to these, the student who intends to become a "general practitioner" has to make himself sufficiently acquainted with the principles and practice of surgery, to be qualified

* The proof that a good medical education was attainable before 1815 may be taken from the fact that there were numerous practitioners in pharmacy at that time capable of forming a Board, and that many of the present examiners must have been educated prior to 1815. The lapse of nearly a quarter of a century has brought others into that situation, and the progress of science may be expected to have rendered them (*ceteris paribus*) superior to their predecessors. I hope that my remarks, so far as they may seem to have reference to gentlemen in the responsible station of examiners, may be received as from *Amicus Curia*, who wishes to see their zeal for improvement tempered by discretion.

* A similar mode of proceeding exists in those cities and large towns of England where courses of medical, surgical, and hospital studies have been lately established, and recognized as capable of conferring qualifications for examinations.

for an examination at the College of Surgeons.

The less industrious and the idle soon begin to neglect some of their studies: finding the disposal of their time uncontrolled, and their attendance at lectures optional, instead of imperative, they gradually withdraw themselves from close attention to any one subject, or perhaps limit it to one or two subjects, flattering themselves with the hope to supply, at some future time, all deficiencies by the aid of a tutor (called grinder) and a printed book of such questions, with answers to those questions, which, as they are informed by interested persons, will be quite sufficient to complete their education, and enable them to accomplish the object of all their hopes and fears.

Admitting that some young men of indolent habits have in this manner, and by a strong exercise of memory, passed through their examinations after a desultory mode of study, having too slender an acquaintance with first principles, they would soon find, and unhappily discover it too late, that the power of retaining and of applying knowledge *so obtained*, is very inferior to that possessed by those of their own school who had acquired their information by diligent attention to a regular course of study; and that their chances of success in the severe duties of professional life would be dissimilar, and bear, I fear, too close a resemblance (allowing for difference of station) to those of Hogarth's industrious and idle apprentice.

I believe this to be a faithful picture of the professional education of students who are destined to become general practitioners in town or country; by which it will be seen that they possess the opportunity of learning enough under the present routine to enable them to fulfil their obligations to society in a respectable manner; but that being obliged to study so many things, and usually doing so within a limited time, the public cannot reasonably expect their education to be "of the highest stamp" in all the following branches, namely, in "chemistry, anatomy, and physiology; anatomical demonstrations, *materia medica*, and "therapeutics; botany, and such other branches of study as may improve the student's general education; dissections; principles and practice of medicine; medical

practice of an hospital; midwifery and diseases of women and children; forensic medicine; midwifery, with attendance on cases*." In addition to these, the student who intends to become a "general practitioner" has to make himself sufficiently acquainted with the principles and practice of surgery, to be qualified for an examination at the College of Surgeons.

It cannot be denied, that most young men who are designed for the higher department of surgery (consulting surgeons) take rather a different course. They are, generally, apprenticed to hospital surgeons, devote a much longer time to practical anatomy and operative surgery, and thus qualify themselves for their future duties. As it is in this manner that such men as Cooper, Brodie, Lawrence, Keate, Earle, Guthrie, Mayo, and other hospital surgeons, have been educated, I think that, on reconsideration, Mr. Norton will have the candour to allow, that the expression, "education of the highest stamp," should be appropriated to practitioners of that class.

It is also customary, I believe, for the medical student, who intends to become a member of the Royal College of Physicians in London, either to enlarge the sphere of his studies, or to devote a much longer time to them before commencing practice, than those young gentlemen who are to be "general practitioners;" but it would be indecorous to carry this parallel to the department in which I am personally engaged.

I trust, then, it will appear that my positions are fairly sustained: first, that a real improvement would be effected in medical education, by the same regularity of attendance at lectures as is required and insisted on, in elementary instruction, at other schools; secondly, that the consulting or hospital surgeon, from the greater extent of his professional education and habitual dexterity, acquired by practice, must be considered as the referee in all important cases of surgery; and that it is probable a physician may not be without the power of contributing to the welfare of society in other cases, where doubts or difficulties occur.

* See printed regulations to be observed by students intending to qualify themselves to practise as Apothecaries in England and Wales, 1835.

Gentlemen already in practice in provincial districts, should lose no time in acting upon the suggestions of Mr. Hill, of Wotton-under-Edge, inserted in the *GAZETTE* of the 7th instant, in order to obtain a just reward for public professional services; or, in the politico-economical phrase of the day, for "the wages of labour." Benevolent and enduring as "general practitioners" usually are, they have families dependent on their personal exertions. They have a right to expect an equitable remuneration for the quantity and quality of professional labour required. They should not submit to be insulted and brow-beaten by such persons as are mentioned by Mr. Hill. I may probably trouble you, at some future time, with a few words on that subject, and a hint at the remedy.

I beg to add, in conclusion, that it is my opinion much benefit has been conferred on the public by the Apothecaries' Act of 1815. The present practitioners in town and country are more equal than before examinations were instituted. Such disparity, however, is found as will arise from superior aptitude, and closer attention to their duties; and this is seen in other professions; but they are all educated to an useful extent, and worthy of public confidence.

I am, sir,

Your obedient servant,

ROBERT MASTERS KERRISON.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

NOTICES OF SIX ELEMENTARY WORKS.

Elements of Anatomy. By JONES QUAIN, M.D. 4th edition, revised and enlarged, illustrated with steel plates, and numerous engravings on wood. Part I., price 12s. Taylor and Walton. 1837.

A Series of Anatomical Plates in Lithography, with References and Physiological Comments, illustrating the Structure of the different parts of the Human Body. Edited by JONES QUAIN, M.D., and W. T. ERASMUS WILSON. Division III. Nerves III. Oct. 1837.

THE great novelty, and, we may add,

improvement in the present edition, consists in the illustrative engravings. Our readers may possibly remember the commendation we bestowed, some two or three years ago, on the work of Mr. Paxton, in consequence of the excellent manner in which the subjects were illustrated by woodcuts introduced into the pages, together with the descriptions, so that there was no turning over of leaves, no searching for the corresponding engraving, but the letter-press and the figure met the eye on the same page. A similar plan is now adopted by Dr. Quain; and as it is admirably adapted to facilitate the study, we have no doubt of the present edition proving a very popular one. When a fifth edition is required, we hope he will adorn it with a still larger supply of engravings; and we take the liberty of suggesting the subject of Hernia as one which might be thus simplified with great advantage to the student. The extent to which the art of engraving on wood has been improved of late years cannot be unknown to the readers of this journal, many of the specimens which we have laid before them being executed in the very best style. The advantage in such works as Dr. Quain's is prodigious; and the facility of working the blocks along with the common types, renders them in every way convenient.

The adjacent specimens taken from the work before us, will enable the reader to judge better than any verbal description. Such a figure as that representing the base of the skull, minute as it is, being placed beside the description,

greatly lessens the student's labour. And the same remark applies to the complex piece of anatomy presented by the muscles of the back, so well displayed in miniature in the other figure.

In the second part, which will complete the volume, we are promised two steel plates, and two plates of the brain. We are not convinced that the anatomy of the brain itself might not be perfectly well displayed by woodcuts; so^{*} amazingly has the skill of some of our artists improved within the last few years*.

The valuable series of Plates undertaken by Dr. Quain also makes steady progress; they continue to merit the commendations formerly bestowed upon them, and promise to form a very complete system of human anatomy. The present part contains two views of the brain.

* It is scarcely worth noticing, perhaps, but in the last and present editions (we have not the others by us to refer to) Dr. Quain, quoting Ovid, makes him say, "Natus est homo," &c., which we cannot scan. It ought to be, "Natus homo est," &c.

The Edinburgh Dissector; or, System of Practical Anatomy, for the Use of Students in the Dissecting-room. By a Fellow of the Royal College of Surgeons in Edinburgh.

STUDENTS will find this to be an exceedingly useful manual. The author (whom we conclude to be the translator into English of Cloquet's Anatomy) informs us, that he has lectured on anatomy for many years; and he is evidently thoroughly familiar with his subject. The first part of the work, comprehending the bones and their articulations, we have particularly examined, and have found to be very clearly and distinctly written. We do not remember having formerly met with the fact, thus stated by the author:—"We have for many years been in the habit of exhibiting the costal cartilages in their dry state, and then shewing the student, that by placing them for a short time in water (a day or two in winter), they will regain all the properties which they possess in the recent subject; and this may be done again and again with the same cartilage."

There are some splenetic remarks at the beginning of the volume, which appear to be misplaced.

We may add, that a good glossary is appended.

Elements of Chemistry; including the recent Discoveries and Doctrines of the Science. By the late EDWARD TURNER, M.D. Sixth Edition, enlarged and revised, by Professor LIEBIG and WILTON G. TURNER. Part I., price 7s. 1837.

THE very high place which the former editions of this volume had taken among the elementary works on chemistry, is a sufficient proof of its merits. Much of the disadvantage which was to be apprehended from the decease of the distinguished author has fortunately been obviated by the arrangements made by his brother, Mr. Wilton Turner. The portion relating to inorganic chemistry, indeed, we are told, was prepared for the press by Dr. Turner before his death; while, in other parts, the present editor has followed out various improvements contemplated by the original author. But the great feature in the present edition is the association of Pro-

fessor Liebig in the task of preparing it. This distinguished chemist enjoys a well-earned reputation for his labours and discoveries in the department of organic chemistry; and this portion of the volume, which we are informed is to be entirely new, has accordingly been intrusted to him. The period at which the different portions are to appear, has been arranged so as to be adapted to the convenience of students attending the winter courses of lectures.

Cyclopædia of Anatomy and Physiology. Edited by ROBERT B. TODD, M.D. Parts X. XI. and XII.

THIS work loses nothing of its interest as it proceeds, and its merits continue such as we have formerly described them. (See our notice, May 14, 1836.)

In the first of the parts which lie before us we have an interesting article on Endosmose, from the pen of Dutrochet, and a very valuable one on Entozoa, from Mr. Owen; while the anatomy of the Extremity, and of the Eye, is minutely and elaborately given—the former by Dr. Todd, and the latter by Dr. Jacob. In Part XI is contained the chemical history of Fat and Fibrin, by Mr. Brande; and interesting articles on Fibrous Tissue, by Mr. Grainger; and on the Fifth Pair of Nerves, by Dr. Alcock. In Part XII. the most important essays are, that on the Fœtus, by Dr. Montgomery; on the Foot, by Dr. Todd and Mr. Dod; while Mr. Grainger contributes a paper on Ganglion.

The whole of the subjects treated of are illustrated by engravings on wood; and if the publishers do not fall into the too common error of extending the number of parts so as to augment the bulk and increase the expense, the work will occupy a place in the libraries of all the literary members of our profession.

Elements of Physiology. By J. MÜLLER, M.D. Translated from the German, with Notes, by WM. BALY, M.R.C.S., &c. Part I.

THE name of Müller has for some years been known to the English reader with progressively increasing reputation. We have ourselves given many of his views and opinions to the world, and some of them coming direct from Berlin, with the advantage of his own re-

vision. Müller is decidedly the great physiologist of the day; and his precise descriptions and methodical ratiocination leave the inconsequential vivisections of Magendie at an immeasurable distance. Mr. Baly, by whom the present treatise has now been executed, is himself a graduate of Berlin, and appears fully adequate to the task he has undertaken. We have looked over various portions of the brochure before us, and find the translation to be marked by clearness and simplicity. It is to consist of three parts; and we are promised the second on the 1st of January. If the two which are to come be executed in a manner as creditable as the first, the work will necessarily become a standard one in this country.

MEDICAL GAZETTE.

Saturday, October 21, 1837.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; polestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

REGULATION OF LUNATIC ASYLUMS.

THE parliamentary campaign is close at hand; in less than a month the combatants will be drawn up in battle array, and so equally are the numbers balanced, that the most sagacious are unable to foretell on which side will be the triumph—*inter utrumque volut Victoria pennis*. The only parliamentary questions, however, which come under our cognizance, are fortunately those which belong not to party nor to faction, but to the great cause of the human race; where, in casting up our votes and anticipating the probabilities of success, we do not ask if A is a whig or a tory, but simply whether he is an honest man. Such topics are military flogging, the starving experiments conducted by our Poor-Law dictators, and the subject of lunatic asylums. From a discussion which took place in the House of Commons shortly before the close of the last

session, it seems probable that lunatic asylums will engage the attention which they deserve during the ensuing one. It appeared that, although the Middlesex Lunatic Asylum has been much and deservedly praised for the excellence of its arrangements and the philanthropic zeal with which it is conducted, the proportion of cures has not been so great as might have been expected. This alone would require some investigation, but other parts of this subject demand a more diligent and minute inquiry; for example, the management of private asylums, and the condition of pauper lunatics in those counties where there are no county asylums, and to these points we are most anxious to direct attention.

Before taking a view of things as they are, let us cast a glance upon them as they were; for in considering the defects of an institution or a system, it is by no means useless to recapitulate what were its acknowledged faults before their partial reformation: in the first place, we thus obtain a full view of the real truth as it existed, plain and unvarnished, before the defenders of the system had learned to gloss it over; and in the second place, we see the extremes which the vices of an institution may reach, when unchecked by the salutary fear of public opinion. Thus, in studying the question of slavery, it is instructive to read the accounts given by eye-witnesses, of its practical working before abolition or mitigation had been agitated. When we read, for instance, in Stedman's Account of Surinam, of the cruelties which he censures, indeed, but of which he does not anticipate the termination, we see to what excesses unlimited power naturally leads, while the disputed atrocities of 1830 are made but too probable by the undisputed ones of 1772*.

Again, if our readers would know into what ignorant barbarities the keepers of lunatic asylums might easily fall, if the most rigorous superintendence were relaxed, they would do well to peruse the Reports of the Parliamentary Committees, appointed to examine into the state of madhouses in 1815 and 1816. They will there find that from the violence used to make patients swallow, the mouth was often lacerated, the teeth forced out, and not unfrequently the patient suffocated.

Corporal chastisement, in its most brutal varieties, was very common. Thus, Captain Dickenson, R. N., was shockingly beaten while confined by means of a chain on his legs, and handcuffs, which rendered it out of his power to ward off the blows which were repeatedly given him on the face and body.

As severe whippings were the most obvious, so they were the most favourite method of procuring a ready obedience from the inmates of madhouses; but they were also the first abuse which it was necessary to lop off. A witness says in her evidence, "Mr. Talbot made this observation to me, 'Mrs. Humieres, we must not follow that practice of flogging Isabella Adams, or else the public will get hold of it; a whip is not to be suffered to be used in our house.'" At this time the whip was used as an engine of punishment: at an earlier period it was considered a most valuable therapeutic agent.

The measures taken to provide for the security of the patients were often worthy only of the darkest ages, and might lead one to suspect an error in the date. Thus, in a Wiltshire mad-

It was then a common practice to cut off a negro's leg as a punishment for running away, and a sure method of preventing a repetition of the offence. (Vol. i. p. 314, edit. 1806.) In one instance the master was more humane; he only cut the tendo Achillis.—(Vol. i. p. 101.)

* Stedman was in Surinam from 1772 to 1777.

house, Dr. Fowler found a man confined in an oblong trough, chained down.

"He had evidently not been in the open air for a considerable time; for when I made them bring him into the open air the man could not endure the light; he was like an Albino blinking; and they acknowledged he had not. Upon asking him how often he had been allowed to get out of the trough, he said, 'perhaps once in a week or ten days, and sometimes not for a fortnight;' he was not in the least violent; he was perfectly calm, and answered the questions put to him rationally; his breathing was then so difficult, that I thought his life likely to be affected by it".

The famous case of Norris will occur to many of our readers; he was fastened to a wall, in Bethlem Hospital, by a complication of chains and rings, and bars, with his right leg chained to a trough, and so secured that he could not repose in any other position than on his back. But perhaps the best account of his case is a transcript of the smith's bill:

"June 23d, 1804, Bethlem; to two bolts and nuts and screws, three feet nine long; to a new round rail-bar for head of bedstead in one of the cells, for Norris, seven feet long; to a new collar for Norris's neck, with two joints to ditto, and two basils for his arms, and five chains, and seven rings to go over the round bar; to two men one day and a half boring holes through brick walls, and fixing the round bar and rivets, and rivetting on the neck-collar and the basil, by order of the committee"†.

And under the date of October 6th, 1804, we find:

"Bethlem; to taking off, and taking to pieces, and lengthening the strap-jointed irons of Norris, and refixing"‡.

A man, named Murphy, was brought

* Minutes of Evidence, taken before the Select Committee appointed to consider of provision being made for the better regulation of Mad-houses in England. Ordered by the House of Commons to be printed, 25th May, 1815. (P. 46.)

† Report of 26th April, 1816, p. 42.

‡ Ibid, p. 43.

from the Batavia Hospital Ship; no harmless method of securing a lunatic having been discovered at the remote period of English history of which we are treating, his arms were cut by the rope with which he was fastened to the stage coach, the whole of the muscles were separated, and the bone was exposed. From the report of July 11, 1815, it appears that this accident, or rather result, was common in Ireland. (P. 24.)

But the state of lunatics, where no mischievousness could be alleged as a motive for extraordinary precaution, was too often miserable in the extreme. Mr. Godfrey Higgins, a Yorkshire magistrate, found concealed cells in the York Asylum. There were four cells, about eight feet square, "in a very horrid and filthy situation, the straw appearing to be almost saturated with urine and excrement." He next found a women's room, twelve feet long by seven feet ten inches, containing thirteen women, who had all come out of their cells that morning. Patients, too, were missing and unaccounted for, and false reports made out.

Other abuses, though great in themselves, may be passed over as small in comparison. Thus the language addressed by keepers to their patients appears to have been coarse and unseemly to the last degree: the lunatics were constantly robbed of the clothes, and comforts, destined for them by their friends; their medical treatment was conducted by the almanack; a bleeding on such a fixed day, and an emetic on another one, &c. &c.

The exhibition of the lunatics in Bethlem to any one who could muster four shillings, was, indeed, a monstrous abuse; it has long been discontinued, but the mention of it may serve to show how strange was the feeling, or rather want of feeling, on this point, in the last century.

In next passing from asylums as they were, to asylums as they are, we are inclined to follow Mr. Browne*, and to exclaim with the French writer whom he quotes, *nos pères n'ont pas renversé toutes les Bastilles!*

Many of the old abuses have been continued through avarice, or even through habit, long after their formal abolition. Thus in the winter of 1820 the Commissioners found a patient, in a private institution, alone in an out-house without a fire, and without shoes; the windows broken. After much shuffling, it was proved that this patient did not sleep in the apartment said to be his, but in a miserable room up a private staircase, concealed by a door, which was discovered with considerable difficulty. It was a single room, small and offensive, containing only a wet and dirty piece of sacking filled with straw, with one rug and a blanket. For this treatment the patient paid 50*l.* per annum†.

Patients have been obliged to remain in bed the whole of Sunday, in order that the keepers might visit their friends; and our only astonishment is that this festival did not occur more frequently than once a week, when we find that, in one asylum, each servant had charge of fifty patients; that in another, 164 patients were intrusted to two keepers; and that, in a third asylum, three keepers were expected to govern 250 patients‡.

To shew how difficult is the extirpation of old errors, the writer whom we have just referred to quotes a curious story of a gentleman who, a few years since, was about to place his brother

under the care of Dr. Fox, of Brislington. "I hope," said the applicant, "you will be as gentle to my brother as you possibly can." "Certainly," said the Doctor. "I know," continued the other, "it is very necessary you should exercise some severity on him; but I hope it will be as gentle as possible." Dr. Fox was at first unable to understand the gentleman's meaning; but it turned out that his theories on the treatment of madness were quite Shakspearian, and that he believed a whip to be the chief remedy employed.

But perhaps the strongest instance that can be alleged, to shew how far we are yet from a due regulation of madhouses, is the case of Willis *alias* Moseley, on which we touched in our article on the Encouragement of Quackery*. The man had been convicted, in October 1836, of keeping an unlicensed madhouse. As he still persisted in the practice, he was brought up for judgment the following January, and sentenced to twelve months' imprisonment, and a fine of 50*l.*

The evidence on the trial went to shew, that the madhouse in question was furnished with iron bars to the upper windows, and had an attached building in the yard, which was fitted up as cells and dungeons, where persons might be unlawfully imprisoned. Mr. Sergeant Adams pronounced sentence, and dwelt very forcibly upon the dangerous purposes to which the cells and dungeons might be applied.

A few months afterwards all the sane and sober were amazed to learn, that the criminal had been liberated. This was done, as appears from a paper published by his friends, under the following shallow pretences.

After his conviction, the prisoner memorialized the Secretary of State, denying the existence of cells, &c., and

* What Asylums were, are, and ought to be: being the substance of five lectures delivered before the managers of the Montrose Royal Lunatic Asylum. By W. A. F. Browne, Surgeon, Medical Superintendent of the Montrose Asylum, &c. Edinburgh and London, 1837.

‡ A useful compendium of the subject, somewhat disfigured by the stiffness of the style.

† Browne, from Report on Pauper Lunatics in Middlesex, p. 155. 1827.

‡ Ibid, p. 147.

praying an inquiry into his case. It was then determined that the Chairman of the Sessions, accompanied by some other magistrates, should go over the building. This was done; and, according to the Willis-alias-Moseley document, "the Chairman found that the formidable building, said to exist in the yard, was in fact nothing but a covered way leading to the stables, and evidently as old as the house. There was no pretence whatever, the Chairman publicly stated, for saying there was any thing like dungeon, cell, or place of restraint. The Chairman reported these facts to the Home Office, and Mr. Moseley was immediately set at liberty."

Now without asking, as some people would do, whether the interval between the conviction and the investigation might not be sufficient for the removal of many engines of restraint, we would simply inquire—

1st, Whether the ordinary cellars of every London house are not as truly cells and dungeons, as any other that could be contrived for the coercion of a maniac?

2dly, Whether, on the supposition that Mr. Willis-Moseley contented himself (as the tenor of his puffs makes it probable) with melancholic patients, and rejected those whose madness was furious, it would not still have been right to allow the law to take its course?

If we wish to prevent the incarceration of the sane, we must be chiefly on our guard in those cases where hypochondriacism may be taken for melancholic madness; in these cases the timid patient, weak in body and irresolute in mind, requires neither cell nor bar; and madhouses may be easily framed, whose moral restraints shall escape the eyes of a whole bench of magistrates.

OPERATIONS AT ST. GEORGE'S HOSPITAL.

Encysted Tumors of Scalp—Removal.—Diseased Wrist—Amputation.—Division of the Tendo Achillis for Club Feet—Novel Operations(?).—Fatty Tumor—Removal.—Hernia—Strangulation nine days—Mortified Bowel.

ON Thursday, October 12th, there were four operations: three by Mr. Keate, and one by Mr. Walker.

Mr. Keate first removed three encysted tumors from the head of a man who had had some already taken away, and one or two more were still left to be removed on a future day. One was of some size, and as the skin adhered much to it, a portion was taken away with the tumor, which adhered so as to require dissecting out, and bled a good deal. The others were turned out easily by pressure at their sides after the scalp had been divided and the surface of the cysts exposed.

Mr. Keate next removed the fore-arm of a man by the circular operation near the wrist, in consequence of disease of twenty years' duration; the joints of the wrist and carpus being extensively ulcerated, with much swelling around them, and very great pain on the parts being at all moved. The case has done well.

The next patient brought in was a little boy of six years of age, whose feet had been deformed from birth; the foot being in both cases turned in, and rotated upwards and inwards, while the toes were at the same time kept pointed by contraction of the tendo Achillis. Mr. Keate inserted a narrow knife, with the flat surface between the skin and the tendon; then turning the edge towards the tendon, it was cut across by the knife, the heel being at the same time drawn downwards, so as to separate the divided ends from one another. An instrument was then fastened upon the foot, so as to inclose it in a strap and kind of shoe, while an iron went up the leg on each side, and was buckled round the leg just below the knee. The shoe part was so contrived as to stretch the back of the leg, and allow of its being still more extended, if necessary, afterwards. The little fellow bore both operations without a single exclamation, and hardly even moved during the time. Mr. Keate afterwards explained the case to the students, and remarked that he had lately seen or heard of this operation having been revived as a new discovery, but that he had often seen it done, and as long as *five-and-thirty years* ago; and that he believed it generally succeeded very well.

A woman then came into the theatre, who had a fatty tumor, of the size of a small melon, on the back of the left shoulder,

which was removed by Mr. Walker. He made a deep cut through the skin, and half way into the tumor, which he then dissected out with the knife, removing some of the fascia and fibres of the trapezius muscle, which adhered to the tumor. There was a good deal of bleeding from the operation, so that the wound was not dressed till some time afterwards, which, indeed, was the case also with the two first patients on whom Mr. Keate operated, in order to avoid secondary hæmorrhage. - Mr. Walker made some remarks on the nature of fatty tumors, which he said were perfectly innocuous, and that they were generally unaffected by medicine, though he had seen one case in which a large fatty tumor of the chin had yielded to *Liquor Potassæ* in large doses, and that there had been no return.

On the following Monday, October 16th, Mr. Hawkins operated for a case of strangulated femoral hernia, in a woman between thirty and forty years of age, the strangulation having taken place on the morning of the Sunday week preceding, so that it had now been strangulated *nine days*. She had been constantly sick since that time, during which she had done nothing except taking six pennyworth of castor oil, and on her admission was in a very low state, apparently suffering much pain, with the bowels so distended that the turns of the intestines could be seen through the abdominal muscles, especially at intervals when the pain came on most violently. The hernia contained a small piece of bowel, intimately adherent to the sac, especially in front, and so lacerable that it gave way, and a little milky fluid escaped. Attempts were made to close the opening by ligature, so as to return it into the abdomen, but the mortified bowel would not hold the silk; it was therefore opened freely, and fastened to the edge of the opening after the stricture was divided. When this was done, some fluid fecal matter escaped, after which a poultice was applied to the wound, with camomile fomentation to the abdomen. At nine o'clock, P.M., five hours after the operation, the patient seemed more comfortable, and lay quietly in bed on her back, instead of constantly tossing about, and had not been sick; no further evacuation, however, had taken place, nor had injections brought away any thing from below the strictured part. Mr. Hawkins passed his finger into the bowel, which seemed to be free; and as there did not appear to be any mechanical impediment, five grains of calomel were given twice, with two drachms of Epsom salts, in infusion of roses and mint-water, every three hours, and some beef-tea and arrow-root were directed to

be given. The next morning, at 7 A.M., about a pint of fluid fecal matter had passed by the wound, and the patient felt much more easy and composed, the pulse being only 102, instead of being as rapid and quick as before the operation, and she had slept several times for a short time. At 1, P.M., she seemed considerably improved, a good deal of fecal matter coming away, and the abdomen being soft and not so distended. She had been sick once after some arrow-root, but had no pain scarcely in the belly, and was cheerful and free from anxiety. A grain of opium, with three of calomel, was given, and the mixture repeated at longer intervals, and the abdomen bandaged with flannel.

On the whole she was much better than could have been expected after so long a strangulation, affording some ground to hope that she might recover, but the amendment of twenty-four hours is far too short a period to be sanguine about after so protracted a strangulation. We shall endeavour to give the sequel of the case in our next number.

HÔPITAL DE LA PITIÉ.

COMMUNICATED BY H. CURLING, Esq.

[Concluded from page 111.]

CASE IV. — *Emphysema; Diseased Auriculo-ventricular Valves; Pneumonia; Abscess.*

A SEMPRESS, aged 30, of a delicate constitution, was admitted into La Pitié, February 20th, under M. Louis. She menstruated for the first time at 13, and was married at 23, but had no children. She has been subject to dyspnoea as long as she can recollect, and has always slept with the head elevated. During the last three years the dyspnoea has much increased, accompanied by palpitations, cough, and accesses of difficulty in breathing, so that she is often obliged to get out of bed during the night, and always sleeps in a sitting position. She has hardly ever been without a cough during this period, even in summer. She has never had the jaundice, and her legs began to swell for the first time six weeks ago, since which time she has kept her bed. She has been in the Hôtel Dieu a short time, and leeches were applied to the anus, on account, she says, of an enlarged liver. Her face has acquired a yellowish tint, and her urine is of a yellow colour. The border of the liver can be felt three inches below the ribs; percussion yields a dull sound to this extent; on pressing suddenly, there is a sensation as if a fluid was interposed between the liver and abdominal parietes. The inferior extremi-

ties, the left arm, and forearm, are œdematous. Percussion yields a dull sound upon percussion in the precordial region; sounds of the heart obscure; slight impulsion; a bruit de râpe after the first sound; the bruit is loudest about three inches above the xiphoid cartilage, and one inch external to it; the bruit can be heard on the right side. Percussion less loud under the right clavicle, for about three inches. A well marked bruit de frottement in this space. Subcrepitation on both sides, inferiorly and posteriorly; a little rhonchus sibilans at the angle of the right scapula, where the patient complains of a pain. Formation of the chest quite natural. To take—

Eau de Vichy, $\frac{1}{3}$ rd of a bottle; Pulv. Opii, gr. i.; nocte sumend. Hirudines x. to the anus.

Feb. 25th.—Sputa always contain traces of blood; appetite diminished; dyspnoea less. The abdomen contains fluid. The liver not diminished in size.

Rep. Med.

27th.—Sputa still streaked with blood; pulse 100, regular and feeble, and offers the same character on both sides. Posteriorly on the right side percussion is obscure in the middle third, and dull in the inferior third; neither bronchophony nor bronchial respiration, but subcrepitation exists less loud and less superficial than on the opposite side; a little craquement at the summit of the same side, for about two inches. Percussion equally loud under both clavicles. No bruit de frottement.

Potassæ Acet., 3ss. in ptisan Pulv. Digitalis, gr. i. bis in die. Pulv. Opii, gr. j. horâ somni sum.

March 5th.—The sputa have a bistre tint. The secretion of urine is much increased, but the œdema has not diminished. On the 9th, percussion was dull under the right clavicle; bronchophony, bronchial respiration, and crepitation, were heard in the same situation. On the 12th there was a well-marked bruit de souffle on the left side, two inches above the xiphoid cartilage, and one from the median line. The pulse was 100, regular, but had a distinct fremitus. The œdema continued to increase. On the 15th she had diarrhœa; her cough was increased; the precordial region was dull upon percussion, but the respiratory murmur could be heard there. There was a little bronchophony under the right clavicle, but no râle. Percussion was not very loud under either clavicle. She died on the 17th inst.

Autopsy 36 hours after death.

Extremities œdematous, more especially

the inferior. The brain healthy; a little infiltration of serum under the arachnoid, and each ventricle contains about half an ounce of a clear fluid. The abdomen contains one pint and a half of a clear limpid yellow fluid; the liver descends about three inches below the ribs.

Pericardium universally adhered to the heart; adhesions very strong, requiring much force to separate them. The heart measures three inches six lines anteriorly in height, and posteriorly three inches; the diameter of the base is three inches eleven lines. The right auricle contains much blood; the thickness of its parietes varies from two and a half to four lines. The right auriculo-ventricular orifice measures only four lines in diameter; its border is irregular, caused by little soft granulations of a yellowish colour, which form a border, projecting about $\frac{1}{3}$ rd of a line, and very easy to raise. The valves preserve their transparency; but the right and left are almost entirely adherent in nearly their whole extent, so that the orifice is much contracted. The pulmonary artery is more voluminous than the aorta, and its parietes are thicker; its ramifications are also larger than usual; no spots are seen on its internal surface. The two borders of the mitral valve are adherent, and the opening very small; the orifice measures only two and a half to three lines in width; its borders are smooth and distinct; the valves are thickened, and the chordæ tendinæ seem to be shortened. The left ventricle is healthy, having five lines in its greatest thickness. The left auricle is thickened, and its parietes firm. Small yellow spots, slightly elevated, are seen on the inner surface of the aorta. The borders of the left lung are rounded; the air vesicles are universally dilated on the surface, having twice their natural volume, and in the superior lobe five or six times. At the base of the same lung near its border is an appendix, formed of dilated air-cell; it is two inches in length and half an inch in width. The right pleura contains about a pint of serum. Several adhesions exist between the left lung and pleura, and its cavity contains Oiss. of serum. The right lung is larger at the summit than at the base; the vesicles are dilated, but compressed by the fluid. At the inferior portion of the superior lobe is a small cavity, lined by a thin membrane, and containing a yellow opaque softened matter; the lung immediately surrounding it light and elastic. A similar cavity near the base of the inferior lobe.

The mucous membrane of the great end of the stomach softened and transparent; large and small intestines healthy. The liver measures six inches in width, seven in height, and about an inch in

thickness; it contains much blood, and is firmer than natural. The gall bladder distended with bile. The spleen and kidneys natural.

CASE V. — *Emphysema — Hypertrophy of the Heart, with Contraction of the Aortic Valves.*

A man, aged 36, of a strong constitution, was admitted under M. Louis, Jan. 23rd, 1837. When 22, he entered the army, and remained in the service ten years. He then followed a business which required but moderate exertion. At 14 years of age he had a very severe illness, and thinks it was an inflammation of the chest. It came on after getting wet from passing over a stream. Some time after that he had an attack of intermittent fever. In 1823, whilst a sergeant in the army, he was laid up in the Military Hospitals of Calais and Besançon for eleven months, with acute rheumatism. The joints of both the superior and inferior extremities were affected. He has never had any venereal affection, and does not often commit excesses. He denies having had at this time a pain in the precordial region, or palpitation. He has always been subject to dyspnœa after every exertion, and was nicknamed "poussif" by his comrades. He has, ever since this time, been subject to pains in his limbs, particularly in wet weather. In March and April of last year the pains were more frequent and severe than usual. In May, without any apparent cause, he for the first time had palpitations, accompanied by a pain in a spot corresponding to the inferior part of the left scapula. He had also a pricking pain in the precordial region, in a circular space of about three inches in extent, and two above the xiphoid cartilage. The dyspnœa increased, the palpitations became more frequent, and three months after he heard a bruit de râpe on the left side. He was obliged to sleep with his head elevated, and to get out of bed during the night, from accesses of dyspnœa. In October, in addition to the pricking sensation, he had a pain in the precordial region. He then entered La Pitié, and was under M. Serres. He was bled, and felt relieved, but only remained fifteen days in the hospital.

The palpitations, dyspnœa, and pain, soon returned. He applied some leeches then, traces of which remain below the left nipple; their application was only followed by temporary relief. Five or six days before his entry all the symptoms became aggravated. His countenance was pale, otherwise healthy. The right side of the chest was natural. On the left side a projection was observed, extending to

within two inches of the clavicle, and two inches below the sixth rib. Laterally it extended from nearly the edge of the sternum to within two inches of the angle of the ribs.

Percussion causes pain in this situation, and is louder than in the corresponding part of the opposite side. A bruit de scie, or de lime, after the first sound, and terminating in a bruit de souffle, is heard throughout this region, but having its maximum of intensity an inch below the nipple, and rather nearer the sternum; it is there also that the pain is greatest. It is also heard posteriorly on the same side, its maximum of intensity being at a point two inches distant, in a transverse direction, from the vertebra, and four from the inferior extremity of the chest, in a vertical direction. The bruit de râpe appears to be more superficial on the right side, and louder than on the left side. Its greatest intensity is at a spot corresponding to the middle of a line drawn from the right nipple to the xiphoid cartilage. The respiratory murmur cannot be heard in the precordial region, and is very feeble below both clavicles; four inches below the right it is inaudible. Posteriorly the respiration is healthy; palpitations constant; pulse 72, strong and regular, not full, but rather contracted. *Fremissement cutané* universal over the chest; slight *fremissement* in the radial artery; a bruit de soufflet in the carotids; no bruit in the femoral artery, but its pulsations seem stronger than usual. His feet and legs have never been swollen. He has but little appetite. He lies on his back, with his head raised. He was bled and cupped with temporary relief. He had an attack of the influenza, when the palpitations diminished.

At present (Feb. 25th) the bruit is much diminished, and is not heard posteriorly; but he still has an acute pain under the left nipple. Eau de Vichy was administered for five weeks, but without any improvement in the symptoms. He was still in the ward when I ceased attending.

REMARKS. — The disease commenced with palpitations and dyspnœa, which would seem to indicate some affection of the heart. Soon after, the patient heard a bruit de lime, and at the same time had an acute pain under the left mamma. A bruit de souffle may exist, and yet the heart be quite healthy; but a bruit de râpe has never been heard without some lesion of that organ being discovered after death—without the existence of contraction of some of the orifices, and consequent hypertrophy. But one important symptom is in this case absent; there has been no œdema of the extremities. Out of

forty-five cases of diseases of the heart, which M. Louis recorded at La Charité, in ten only was there no œdema during life. In eight out of this number there was no contraction of the orifices, so that in two only contraction of the orifices existed without œdema. The others were cases of hypertrophy, without complication. One of these two cases was that of an individual who, after a sudden strain, was attacked with palpitations; a bruit de scie was developed, being loudest on the right side. The symptoms continued for eight years, without the extremities becoming œdematous. The disease was thought to be aneurism of the aorta. After death the aortic orifice was found to be diminished to the size of a small fissure, eight lines in length.

There is no reason, then, that a contraction of one of the orifices should not be admitted in this case. The bruit is loudest on the right side, and not at a point corresponding to the aorta. If the aortic valves are diseased, the heart must be increased in size, which, by displacing the aorta, would account for the sound being loudest in that particular situation. Percussion affording a louder sound on the left side, would, however, seem to indicate that the heart had rather diminished in volume. The existence of very extensive emphysema on the left side would account for the loud sound upon percussion, which is rendered more probable by the projection on the same side, and by the long duration of the dyspnoea, and its presence at a period prior to the commencement of the palpitations. Besides, in eleven cases out of twenty-three, emphysema occupies the left lung. There is one fact against this supposition: the respiratory murmur, which ought to be more feeble than on the opposite side, was, if any thing, louder. Might not the bruit de scie, on the right side, mask the respiratory murmur?

What was the primary cause of this organic disease? Is it to be referred to the attack of rheumatism, which occurred fourteen years ago? The palpitations and the pain only made their appearance ten months back. M. Louis was of opinion that the affection of the heart had no connexion with the former attack of rheumatism. The patient was not asked if he had experienced palpitations and a pain; but he was asked if they were as severe then as they were ten months ago. He distinctly stated, that he had neither pain nor palpitations at that period. The question was often repeated, but always with the same result.

ACCIDENTS AT THE LONDON HOSPITAL.

Surgeon for the week, Mr. LUKE.

Assistant Surgeon, Mr. CURLING.

Fractured ribs, 5; contusion of the hip, 1; compound fracture of the tibia, 1; severe burn, 1; contused foot, 2; dislocation of the jaw, and contusions on the face, 1; cut on the head, 3; fractured humerus, 1; ruptured intestine, and fractured femur, (a) 1; contused elbow, 2; contused ankle, 3; contused hand, 1; bite on the hand by a pig, 1; fractured fibula, 1; severe laceration of the integuments of the thigh, 1; fractured femur, 2; incised wound on the face, 1; contusion on the knee, 1; inguinal hernia (reduced), 1; contused wound on the head, 1; contused knee, 1; contused wrist, 1; contused side, 1; bite on the foot by a rabid dog (parts excised), 1; strangulated femoral hernia (operated on), (b) 1.

Accidents admitted as in-patients	
during the week	35
Out-patients	55
Total	90

(a). This man received his injuries from the fall of a scaffold on which he was at work. He was brought to the hospital at noon in a state of great prostration, from which he never rallied, but died at nine in the evening. On examination of the body there was found a transverse laceration of the duodenum, just at its termination in the jejunum, with feculent matter in the cellular tissue around, and a small quantity also in the peritoneal cavity, which had passed through a slight laceration in the mesocolon.

(b). In this case the attempt was made to divide the stricture without opening the sac, but it was unsuccessful. The gut had only been down nine hours, and was closely girt at the neck of the sac. The bowels were relieved within a few hours after the operation and the patient is recovering.

The five cases of fractured ribs were unattended with emphysema, and at the last visit of the surgeon were doing well.

NEW EXPERIMENTS ON THE TORPEDO.

M. MATTEUCCI has communicated to the Académie des Sciences the results of his observations, made in June and July last, on 116 living torpedos which he was enabled to examine, in some instances, immediately after they were taken out of the

water, at Casenatico, on the shores of the Adriatic, whither he went expressly.

Besides the common galvanometer, he employed frogs; which show, he says, the direction of the current when passing from one foot to the other; the limb which contracts being that in which the current passed in the direction of the branching of the nerves.

It is said that a liquid is passed into the organ to produce the discharge, and also that this act is accompanied by violent muscular contractions: in either case there ought to be change of size or form, and yet none was evident, as he found by a very simple experiment.

According to M. M., no manifestation of electricity is obtained if the animal be not touched at once in two different points. Thus an isolated frog, which touched the torpedo's body by one of its nervous filaments, received no shock. The torpedo has not, as is generally believed, the power of directing the discharge to this or that point at will. When endowed with great vitality, discharges may be obtained from all parts of the body; but afterwards, the power is found limited to the regions situated above the two electric organs.

The distribution of the electric fluid is governed, according to M. Matteucci, by the three following laws:—

1st, All the points of the back are positive with respect to all those of the belly.

2d, The points of the dorsal surface, situated above the nerves which penetrate the organ, are positive with regard to the other points of the same surface.

3d, The centre is on the ventral surface. In relation to the course of the current in the interior of the organ, the layer which touches the dorsal skin, or which is nearest to this part, is always positive with regard to the layer contiguous to the ventral skin.

The intensity of the current varies in proportion to the extent of the layers which touch the two surfaces of the organ. When the animal has great vitality, the current traverses, without sensible weakening, a great mass of salt water, even divided by metallic diaphragms; but the transmission becomes less powerful as the animal loses its strength. To obtain the spark, the author used a different proceeding to what he first intended,—merely placing the animal between two metallic plates, which communicated by two gold leaves.

All the skin, muscles, and ligaments, attached to the organ, may be cut off, without the intensity of the discharge being sensibly diminished. Even three-fourths of the substance of the organ may be cut away, and yet shocks be obtained; but the

ligature of the nerves puts a complete stop to them. The medulla oblongata and medulla spinalis may be divided without the discharges ceasing. As to the brain, it is only the fourth lobe which cannot be touched without a discharge taking place, and this, which may be called the electric lobe, being once removed, all the phenomena of electricity are put an end to. It must be observed, however, that the nerves of the organ itself, after separating it from the brain, may still give some discharges, if irritated, immediately after this separation.

When the torpedo is weakened, so that it can no longer give shocks, very strong ones may still be obtained, and these even stronger than those which it gave in its greatest activity, by touching the electric lobe. The action of the lobe in this case, says M. Matteucci, is direct; that is, if the right side be touched, it is the right organ which gives the discharge. This is the only method by which discharges can be obtained from one side only. When discharges can no longer be obtained by touching this lobe, which is the case only some seconds after the death of the animal, very energetic ones may still be obtained by wounding the organ deeply; but in this case the discharges have no longer the constant direction from the back of the belly.—*La Gazette Médicale*, Oct. 7.

M. VELPEAU'S TREATMENT OF FRACTURES.

M. VELPEAU read a paper on this subject at the Academy of Sciences, on Sept. 25. At the present day two methods are employed by practitioners: in the one, the apparatus is not applied till effusion has taken place in the limb; in the other, they act on the supposition that a moderate compression hastens the effusion, and lessens the inflammation. M. Velpeau is of opinion that in all fractures, even in those which are accompanied by wounds of the integuments, we should proceed immediately to the reduction.

The fracture being reduced, he surrounds the limb, from the roots of the fingers or toes, up to its proximal extremity, with a slightly-compressing bandage, so as to maintain the fractured pieces in a convenient position; and instead of using splints and compresses, he makes the envelope itself, which the bandage forms, stiff. He at first thought of using for this purpose the solidifying liquid of M. Larrey (albumen), but afterwards he found it preferable for the purpose to make use of starch, prepared after the method used by washerwomen, in imitation of the example of M. Sentin, of Brussels. This latter surgeon, however, uses a different

apparatus—viz. a double Sculletus' bandage, and splints of double layers of card-board.

The dressing of the whole apparatus is effected in from two to four days. When this has once taken place, the limb and the bandage are so exactly moulded to one another, that displacement is impossible. The compression being every where equal and moderate, supports the tissues, and does not produce any inconvenience. The patients can turn themselves and move about in their beds as if they had only a simple contusion of the leg. They are not obliged to remain confined and immovable for six weeks or two months; but may, without inconvenience, sit up on rather a high seat (for they may slightly fix the leg,) and may walk about with the assistance of crutches, and supporting the foot in a great stirrup tied round the neck.—*Ibid.*

SUGAR OF LEAD PILLS.

To the Editor of the Medical Gazette.

SIR,

In my letter on the Treatment of Cholera, published by you last week, I spoke of pills made of acetate of lead and opium; it may be well to remark, that the most convenient way of making these pills is to add five or six grains of powdered liquorice to the scruple of acetate of lead. They may be readily mixed into a mass by means of mucilage of gum Arabic.—I am, sir,

Your obedient servant,

ROBERT J. GRAVES.

Dublin,
18th October, 1837.

CHARLES HENRY ADAMS.

NOTICES.

We cannot insert the letter signed "A Non-Tripartite."

OBSERVER, on Naval Surgeons, is under consideration.

OBSERVER, who abuses University College, wants point, and we think is unfair in attacking a Professor of whose merits or demerits he cannot possibly have yet had time to judge. By the way, his own proposed motto is a false quotation: *etiam* ought to be *et*.

We cannot make room for Dr. Howison's papers on Botany. Nos. 1 and 2 have, therefore, been returned to the publishers.

ERRATUM.—In Mr. Chapman's paper, in our last number, page 98, col. 2, lines 41 and 42, for "capillaries," read "absorbents."

Medicine and the Collateral Sciences.

SATURDAY, OCTOBER 28, 1837.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE V.

On the Nature and Properties of Sound — Sound a kind of motion — Explanation of Vibrations of Sound — Vibrations of Cords, of Solids, Liquids, and Air — Effect of Sound on the Molecules of Bodies — Explanation of Duration of Sound — of Pitch, Harmony, and Discord — Conduction of Sound — Reflection of Sound — Modified Echoes — Sources of Sound — Modes of Increasing and Transferring Sound — Sounding-boards — Ear Trumpets — Difference between the Reflections of Sound and Light.

Now, gentlemen, to supply us with what we found needful in the last lecture, I am going to give you a brief explanation of the nature and properties of Sound. Perhaps you will be disappointed at finding that I do not propose to exhibit to you the various kinds of apparatus and instruments, by which lectures on acoustics are made attractive, if not instructing. I purposely avoid every illustration but those of the simplest and commonest kind; and if I can judge by my own experience, you will learn more of the nature and laws of sound by reflection on facts and pheno-

mena that are always within your reach, than by the most striking and wonderful displays wrought by the complete apparatus of the lecturer.

Let us begin with the abstract question, what is sound? *Sound* is not a matter, a separate thing; it is a condition of matter. It is a *particular kind of motion* in matter; and this motion being communicated to the matter in contact with our organs of hearing, produces that physiological impression which we call sound. This same motion, when examined by another sense, as sight or touch, can often be seen or felt to be motion. Thus, when I strike a cord of this guitar, I not only hear the sound, but see and feel it move. We shall find hereafter many cases in which we can feel the motions of sound; and in all other instances where we hear sound, we know there must be motion. Our organs of hearing are more sensitive of this motion than our eyes or our fingers; they can feel finer degrees of it, because they are specially adapted to it.

But what kind of motion is this which constitutes sound? It is not a slowness of motion; for, as you perceive when I move this stick slowly through the air, it gives no sound. Neither will mere velocity of motion suffice; for, as you know, the earth is moving with great velocity, "without a whisper in its silent course." Now observe, by an example, what sort of motion produces sound. When I move this stick against something which offers resistance to it, as when it strikes this table, it gives sound; or when I move it so quickly through the air that the air resists it, we then have sound. Besides *motion*, then, we must have *resistance*; and this is so essential an element of sound, that I have ventured to define sound to be *resisted motion*, or more exactly, *motion of a certain force resisted by a certain force*. The moving force, and the resisting force, impelling the matter alternately to and fro, in oppo-

site ways, constitute what are called the *vibrations of sound*.

This word *vibration* is a very good one for us, because it describes the nature of sound better than the words *wave*, *undulation*, *pulse*, &c., which rather imply the relations of sound to distance, and are less simple in their signification. Now if you want to understand what vibrations are, look at the bass cord of this guitar; it is now slack, and when I touch it you can follow, and almost count, its to-and-fro motions with your eye; these motions give no sound, or only a slight flutter, which is accidental. But observe how, as I gradually tighten the cord, its motions become quicker; and now you hear a sound. Now the silent vibrations which you could follow with your eye are precisely of the same kind as those which produce sound, except that they are slower; so are the vibrations of a pendulum: and as we can watch these, let us study in them the nature of vibrations in general. When I move this pendulum out of the perpendicular, and then let it go, you see it not only falls back to the perpendicular, but its momentum carries it beyond, to describe part of a circle on the opposite side, from whence it again sways back, past the perpendicular, to the side from which it started; and so on, backwards and forwards, for some time. Now the cause of these vibrations are two opposite forces, which alternately predominate—the disturbing motion or momentum, and gravitation. So, also, in the vibrations of a cord or wire fixed at both ends, the opposite forces are the disturbing force or momentum, and the elasticity of the cord; the first carrying the cord out of a straight line, and the latter tending to restore it to it. But I must not dwell too long on elements that may be known to you already; or that may, at all events, be mastered by a little reflection.

You will perhaps say, this is all plain enough in the case of a pendulum or a cord, but how can solid bodies, or liquids, or air, vibrate? Where are the contending forces here? I answer to this, just reflect a minute on the intimate constitution of these bodies. All matter is composed of molecules, which are held in their places by certain mutual forces of attraction and repulsion, which resist any forces tending to displace them. And now mark me, this resistance is not absolute, but of the same kind as the resistance which these guitar cords offer to my fingers; they yield for the moment, but spring back again, and vibrate to and fro until they recover their state of rest. It is an *elastic resistance*; and it is this property which constitutes in bodies what is called *molecular elasticity*. I will illustrate this by a

diagram that will very well represent the vibrations of molecules.

Suppose the molecules of matter to be elastic spheres or spheroids (which, if not in themselves, yet, in their spheres of attraction and repulsion, they certainly are), we may represent them thus—

If an impulse be communicated to the first of these elastic spheres, the first effect will be to flatten it thus—

But its elasticity causes a reaction, which not only restores its shape, and communicates the impulse and flattening to the next molecule, thus—

but springs beyond it into an oval of the opposite direction, the original impulse having been then transmitted to a further molecule, thus—

There is then another reaction, which throws it beyond its spherical into its first oval shape; and so on until the equilibrium of forces is restored, a molecule is rapidly undergoing all these changes—

Now this very diagram, which represents the changes which constitute the vibrations of a single molecule in a certain period of time, will also serve to shew how an impulse, and the vibrations which it causes, are propagated through distance, along a series of molecules; this is *propagation*, or *conduction of sound*. You will now, too, perceive what is meant by a *wave* or *pulse of sound*, which I just now said is a more complicated thing than a vibration. It is, in fact, a series of molecules in the different stages of a vibration. Thus, in the diagram above, every five molecules contain a wave, the last being in the same condition as the first, and being ready to go through the same series of changes again. As I have not time for much explanation, I have constructed the diagram below, which exhibits more fully these waves, and the changes that constitute them. You are not to suppose that it is mathematically exact, but it exhibits very well the principle of the phenomenon; and

if it sets you a-thinking, you will, making allowances for the necessary corrections, get from it a better notion of the nature and phenomena of sound, than from any of the usual illustrations. It represents the progress of an impulse, followed by its opposite reaction, through a triple row of spherical molecules, which are seen beyond *e* in their state of rest; the impulse,

which began at *a*, not having reached them. The successive waves or pulses, *d*, *c*, *b*, are the results of the alternation of the impulse and resisting, or reacting forces, before explained; and you see how an impulse, impressed on a single molecule (*a*), is communicated, laterally as well as in a direct line, just as we know sound to be.

By substituting elliptical molecules, we might represent the sonorous properties of those bodies that have a polarity, or whose density is greater in one direction than in another, as in the case of wood.

Well, then, having seen what sort of a motion that of sound is, and how it spreads itself through bodies, let us bestow a few minutes on the differences of quality of sound. Why does this piece of metal give a long ringing note, whilst this piece of wood, when struck in the same way, yields only a short knock? It is because there is a greater equality in the molecular elasticity of the metal, so that the molecules continue to vibrate without interfering with each other. Let us illustrate this by the pendulum. Here are two pendula; and you see, when I set them in motion, they swing harmoniously together, without interfering with each other, because they are of the same length, and therefore vibrate in the same time. Now I shorten one of them a little: now you see their times of vibration do not correspond, and they soon clash and stop each other's motions. It is just the same with the molecules of different bodies. Where their elasticity is uniform throughout the mass, the molecules vibrate in the same time; and not interfering with each other, the vibrations are continued, and constitute a note or tone, as in a simple piece of metal or glass. The molecular elasticity of wood, on the other hand, is not uniform; some molecules vibrate quicker than others, and the vibrations are consequently soon stopped. In softer bodies the molecular elasticity is still less uniform; their vibrations are therefore still shorter, and less perfect; they scarcely yield any sound; and they can choke the vibrations of other bodies with which they are in contact. Thus, see how little sound I get by striking this cloth; and when I bring this tuning-fork, which is sounding, in contact with it, the vibrations are immediately stopped. Yet we can get a sound out of

this cloth; and remark how: by stretching it until it is tight, which increases and renders more uniform the elasticity of its molecules. Observe the same thing in this piece of membrane: whilst it is loose and flaccid, it scarcely gives any sound; but when I stretch it on this ring, it becomes quite a little drum. You see, then, why some bodies are sonorous, and others not.

Let us take up another difference, that of *note*, or *pitch*. Why does this short piece of metal, when struck, give a high sharp sound, whilst this long bar gives a low bass note? Because its vibrations are quicker; and it is an ultimate fact, that the sensations of shrillness, or deepness, in sound, depend on the number of the vibrations in a given time. You shall see the proof of this. Here is a long steel wire, fixed at one end: it now vibrates so slowly, that you can count the vibrations; but it produces no sound. I shorten it, it vibrates more quickly; and now it gives a low tone. I shorten it more; you see it vibrates still more quickly, and the tone is raised. I now fasten it much shorter; you hear how sharp the tone is; but the motions are so rapid, that you can scarcely see them. Observe the same corresponding changes of phenomena as I loosen or tighten the cord of this guitar. Again, when I blow into this short tube, you have a shrill note; with this long one the note is deep. You cannot see the vibrations here, because the vibrating body is air; but you can easily understand that a short column of air will move more quickly than a long one; and when I blow hard into the long one, I get a note an octave or more above, because the force of the blast increases the elasticity of the column, which therefore doubles its vibrations. I could add many amusing illustrations, but our time allows me to add only a word or two on a subject immediately connected with this—harmony and discord. When two sounds strike the ear at the same time,

their vibrations will either combine or not, according as their numbers correspond or not in some simple arithmetical ratio. Thus, when a sound of 10 vibrations in a second strikes the ear at the same time with another of 10, the sounds will combine, and form the harmony of *unison*. Again, when one of 10 occurs at the same time with one of 80, the vibrations unite in the regular proportion of one to two, and the harmony of the *octave* results. So also with concords of the *third*, the *fourth*, the *fifth*, &c., there is a simple arithmetical relation by which their vibrations can unite; but when sounds of such numbers as 40 and 45, 40 and 53, and the like, occur together, their vibrations cannot coalesce, but, affecting the ear with conflicting motions, produce the impression called *discord*.

Conduction of sound is the transmission of sonorous vibrations through bodies: and this obviously depends on the same properties, of strength and uniformity of molecular elasticity, which render bodies sonorous; and I shall merely illustrate this by an experiment. This tuning-fork, when struck, gives very little sound as long as it is held between the fingers; but when its vibrations reach the sounding-board of this guitar, its note becomes loud and clear. Now, by placing different bodies as means of communication between the tuning-fork and the guitar, we may judge comparatively of their conducting power. Through this long deal rod you perceive the sound is conducted very well; the longitudinal fibres of this wood are very rigid and uniform, and its lightness makes it easily receive the vibrations of contiguous bodies. This iron rod, too, answers well, for its molecules are strongly and uniformly elastic, and resemble those of the tuning-fork, in which the vibrations begin. But observe, when I substitute this handkerchief, or this sponge, although the distance is much less, the sound is not transmitted through them. When I draw the handkerchief tight, you can then just hear the sound feebly transmitted. Rigidity, or uniformity of tension, then, and similarity in density, or lightness of mass, are the qualities which render bodies good conductors of sound; and the opposite qualities make them bad conductors, which either do not receive the vibrations, or, receiving them, promptly choke them.

I have just said that some bodies do not receive the vibrations from other bodies; neither do they destroy them. What becomes of them, then? They are *reflected* back into the media from which they come. Now *reflection of sound* is an important phenomenon, and we must look into it a little.

Suppose some light body—such as a cork ball, or an air-bladder—to strike a hard heavy body, such as a ball of metal; it would communicate little or none of its motion to the metal ball, but would rebound from it—that is, its motion would be thrown back upon itself. It is just so with the motions of sound. When the molecules of a light body, such as air, vibrate in contact with a hard body of much greater density, such as a stone wall, the motions are scarcely communicated to this body, but are reflected back; and this the more completely as the contrast between the density of the two bodies is greater. Now such a reflection of sound at a distance, you know, constitutes what is called an *echo*: here the reflected sound arrives at the ear later than the original sound, by the time which it has taken to travel to the reflecting surface and back. Sound travels through air at the rate of 1130 feet in a second; so you can easily perceive, that at short distances, unless the reflections be repeated several times, the reflected sound will not be distinct from the original sound, and there will be no echo. Now in large rooms, particularly when empty, the reflections are repeated many times, and you therefore hear a reverberation more or less continued, and generally altered by the reflection: but it is in small chambers, or cavities, of from six or eight feet down to two or three inches in diameter, that echoes present the most remarkable modification of a ringing or tinkling kind. This is what you may hear in empty barrels, bottles, and other hollow objects. When any sound or impulse reaches the air within them, it is reflected from side to side so rapidly that the number of reflections becomes as the number of vibrations, and gives a note the pitch of which is determined by the relation which the diameter of the cavity bears to the velocity at which sound travels through air. This subject requires a little consideration to understand it; but you will find in it the explanation of several phenomena intimately connected with the subjects to come before us. We have no time to dwell on it now.

We have seen that a certain kind of resisted motion constitutes sound: we have now to run rapidly over a few instances of this, in various modes of producing sound. The most familiar modes of producing sounds in solids are by percussion, collision, and friction. The two latter are, in fact, modifications of percussion, consisting of repeated percussions of the particles of the surfaces or edges of bodies. When these percussions are repeated with a certain quickness and regularity, they constitute a continued note. This cord is

wound round with wire which forms a series of rings on it: when I rub the edges of this card slowly along it, it produces a *click* at each ring, and you only hear a succession of clicks; but when I pass the card rapidly, you do not hear the click, but a continued note, and this note is higher the quicker I move the card. Such sounds I call *click-notes*. They are not very musical, but they are interesting, as they present us with an analysis of many common sounds. The notes of the cords and wires of musical instruments, and of the parchment of the drum, need no comment: they are the result of the vibration of bodies rendered uniformly and freely elastic by artificial tension. Sounds depending on the vibration of air are instanced in explosions, and in the notes of the flute, pan-pipe, whistle, &c. These are most readily conducted by air. Many sounds result from the combined motions of solids and air; the solid opposing a vibrating resistance to the passage of a current of air, and communicating its vibrations to the current. Such are the notes of reed instruments, trumpets, the æolina, &c.; and I believe that the human voice may be classed among them. Observe what a variety of notes I can get by blowing through this tube, with a thin piece of India-rubber stretched over the end of it. These are the same kinds of notes as those of the human voice; rather a cracked one, I admit, yet I have heard worse notes sung, and you will see the instrument is quite a rough and extemporaneous one. By drawing the India-rubber tighter, the tone is raised at pleasure. I have no doubt that we might, by a little coaxing, make the note more mellow; and it requires only a little mechanism to divide this note into articulate sounds. But I leave it for others to make this artificial voice speak; it has said enough for us.

There are certain modes of increasing and transferring sound, which we must just advert to. When I strike this tuning-fork, and hold its vibrating end at the mouth hole of this flute, it produces no sound unless I stop up some of the finger-holes, so as to produce the fingering of a note in unison, or in close harmony, with that of the tuning fork; and then observe what a clear note comes forth. The column of air in the instrument so adjusted, has just that degree of elasticity that enables it to vibrate in unison with the tuning-fork, the notes of which it reciprocates. A cord tuned in unison will also reciprocate in like manner. Sounding-boards of stringed instruments are constructed with hollows of varying depth, that the air within them may reciprocate the different notes of the cords; but the chief use of sounding-boards is to assist in

transferring the vibrations of the solid wire, or cord, to a large surface of the air, which is so much more rare and yielding that it is but little impressed by the motions of so small a body as the cord alone. You have already seen this illustrated with the tuning fork and the sounding-board of the guitar; but now you may perceive that this board, which has no hollow, answers in a less degree. The knowledge of these facts enabled Mr. Wheatstone, some years ago, to astonish the public with his *enchanted lyre*; which was merely a sounding board, communicating by a small rod of wood, or metal, with the sounding-board of a pianoforte concealed in another room.

Sounds produced in air may be directed and concentrated by reflecting surfaces. It is on this principle that ear-trumpets and speaking-trumpets are constructed. The former ought to be so made as to receive the greatest possible body of vibrating particles, and to concentrate them by as few reflections and turns as possible. If you go into the shops, you will find very few instruments in which these points are attended to. The greater number render the speaker's voice noisy enough, but they sadly confound his words. A large cone of pasteboard, with a short curved tube from its apex for the ear, makes as good an ear trumpet as can be constructed; and we only want a little mechanical ingenuity to contrive one of this shape that shall be also portable, to bring it into general use. One word more on reflection of sound, which is applicable to this subject. It is generally said that the reflection of sound from a plane surface takes place like that of light, at an angle equal to that in which it fell on it. This is true with regard to sounds at some distance; but when a sonorous pulse of air approaches a reflecting surface, by compressing the layer of air next the surface, it increases the elasticity of that layer, so that it begins to be reflected, or rather *refracted*, before it reaches the reflecting solid. Its course, therefore, instead of being like that of light, thus —

is turned in a course thus—

This is the reason why it is not necessary to construct instruments for concentrating sound by reflection, with the nicety that is indispensable in those for reflecting light; and it is by a similar property that close tubes of air have the power of conducting sound so much further than open ones. But we must conclude this subject, and in the next lecture take up the acoustics of the chest.

If you wish to study sound further—and you would find it both amusing and instructive to do so—I should advise you to consult Sir J. Herschell's Essay, in the *Encyclopædia Metropolitana*, and Dr. Arnot's *Elements of Physics*. These works do not contain all that I have been giving you; for having a new application of acoustics to deal with, I have found it necessary to investigate properties of sound which had not been fully studied before. This investigation has been so far successful, as to enable me to reduce to simple principles all the acoustic phenomena which we have to consider; and I now hope that these principles will prove as intelligible and instructive to you as they have been to me.

LECTURES

ON

RHEUMATISM AND ITS EFFECTS;

By R. MACLEOD, M.D.

Physician to St. George's Hospital.

LECTURE II.

An inflammatory affection of the Heart and its Membranes the most common complication of Rheumatic Fever; this long known in England, though but lately in France—M. Bouillaud's views—Class of cases in which Pericarditis is most frequent; this occurrence erroneously attributed to Blood-letting—Local Symptoms of Pericarditis—Auscultation and Percussion—General Symptoms—Importance of attending to the Expression and Posture of the patient.

By far the most common, as well as the most important, complication of rheumatic fever, is an affection of the heart. Cases of this nature were recorded, now half a century ago, by Dr. Piteairn, since which time many English physicians have written upon the subject, so that the fact of the heart being occasionally subject to inflammation during the existence of acute rheumatism, has long been an established pathological principle in this country. Under these circumstances, it is rather startling to find M. Bouillaud, in 1836,

not, indeed, claiming as a discovery of his own, the fact of pericarditis sometimes occurring in rheumatism, but maintaining that the doctrine of such complication being any thing more than accidental, rests upon the authority of his researches, and which, according to his own account, had only been fully made out during the three previous years.

Ever ready, as some among us are, to attribute to our neighbours in France the superiority in pathological anatomy, it is not a little remarkable to meet with an illustration so palpable as this of the neglect of that which alone can render such investigations practically useful; I mean the application of the knowledge acquired from studying the changes of structure in the dead to the explanation of disease while yet progressive in the living. The observations of M. Bouillaud—more especially his claim to originality—clearly show that, among his countrymen, the closeness of the connexion between rheumatism and carditis was not known; and accordingly, when we turn to the best French authorities, we find that the subject is either altogether omitted or but slightly alluded to. Corvisart, indeed, says he is inclined to regard gouty and rheumatic affections as frequently producing adhesion of the pericardium; but, speaking of the causes of pericarditis, he does not even allude to the coincidence of this disease with rheumatism. The same want of any distinct announcement of the connexion between rheumatism and pericarditis, characterizes the volumes of Laennec, and the more recent works of Chomel. But what is still more remarkable, Louis, in his *Memoir on Pericarditis*, in which the phenomena of the disease, as regards its local and general symptoms, are excellently detailed, says nothing of its connexion with rheumatism. Of all the French writers previously to M. Bouillaud, Andral is the one who makes the most distinct reference to a connexion between acute rheumatism and certain affections of the heart. He relates (in his *Clinique Médicale*, tom. i. 2d edit.) a case of pericarditis which followed an attack of rheumatism, speaking of it as a *metastasis*; but one which he seems to have thought quite as likely to attack the pleura or the lungs as the heart; and he adds that the lesion of function in such cases appears to be greater than the change of structure: expressions which show how little familiar he was with the phenomena in question.

But if M. Bouillaud be not entitled to the merit of priority in establishing the important relation which subsists between acute rheumatism and inflammation of the heart, he deserves credit for the zeal and activity with which he has investigated the subject. Since his attention was

directed to the inquiry, he has met with so many instances of rheumatism of the heart, that he estimates them at not less than one-half of the whole number in which the disease has assumed the character of rheumatic fever. Indeed he goes farther, and assumes the coincidence of the heart affection with acute rheumatism to be the rule, and its absence the exception. Without carrying our opinions quite so far as this, no one who has been much in any of our public hospitals of late years, can fail to have been struck with the very large proportion which the cases of diseased heart bear to the mass of those admitted; and if he has carried his inquiry but a single step farther, he must also have found that a great majority of those labouring under such affections have had rheumatic fever at some previous period, although it often happens that they themselves have not suspected any connexion between the primary acute attack and the secondary chronic disease.

When attention was first directed to the affection of the heart in rheumatism, it was very generally supposed, and is still frequently assumed, that this depended upon a metastasis or change of seat on the part of the rheumatic inflammation: but more extended observation has not confirmed this view, and I have myself so frequently seen cases in which the supervention of carditis was attended by no mitigation of the external rheumatism, that it seems to me quite illogical to apply the term metastasis to this condition. Again, I have known an individual who had been exposed to cold, become affected with pericarditis, having had no pain of the limbs previously, but who has had unequivocal rheumatism in some of the external parts within twenty-four hours after the heart had become affected. The result of my experience, indeed, would lead me to infer, that if an individual has any given set of joints affected with acute rheumatism, such joints are more likely to be relieved if the disease attacks other external parts than if it fix upon the heart. It is probably because we often see that when a second set of parts about the limbs become implicated, those which were first attacked improve, that so many writers have assumed the same to occur with respect to the heart. The pericarditis supervening during rheumatic fever, then, may more correctly be regarded as an extension of the disease, than as a true metastasis.

Another important question relates to the class of cases in which this complication presents itself. Dr. Latham says, "it is incident to all the degrees, and all the stages, and all the forms of acute rheumatism." I fear it will not add to

the credibility of my opinions, that they differ from so esteemed an authority. I acknowledge, indeed, that it is incident to all degrees of rheumatism; but when it is added, "it is not more to be looked for when the disease is severe than when it is mild," I am under the necessity of withholding my assent. According to my experience, the heart affection is much more frequent in severe than mild cases of rheumatism. I do not mean to say that I have not seen pericarditis come on where the external rheumatism has been mild; but merely this—that such examples are rare, compared to those in which the reverse is the case.

Neither do I think that it is equally incident "to all forms of acute rheumatism." Indeed, on referring to my notes, I do not find that any of the cases of heart affection which I have witnessed (save one) have resulted except from one particular form—namely, the general or diffuse kind; in which the fibrous structures are chiefly implicated. It is but right to remark, however, that when Dr. Latham speaks of the heart affection as liable to supervene upon all the forms of "acute rheumatism," he may possibly limit the epithet "*acute*" to that form in which the fibrous textures are the seat of the inflammation.

As some persons labouring under rheumatic fever have, while others escape, an affection of the heart, it becomes a very important question to ascertain the cause of this difference. I am not aware that any circumstance has been specified as tending to produce the pericarditis in such cases, except blood-letting, which has been supposed to increase the risk of this occurrence. So far as my observation extends, this opinion rests on insufficient grounds. I have in many instances, during the last few years, bled patients largely and repeatedly in rheumatism, without as yet having met with one instance in which inflammation of the heart has been induced by it; and I have seen many cases of rheumatic heart, in which the patients had never been bled at all. At Edinburgh, some years ago, blood letting was practised to a great extent in the clinical wards of the Royal Infirmary; and Dr. Watson, who witnessed the treatment, says, in reference to it, "I do not recollect that affections of the heart were much noticed in those cases." Again, blood-letting has scarcely been employed in France in the treatment of rheumatism, and yet M. Bouillaud, as I have said, alluding to the frequency of the complication of pericarditis, regards its presence as the rule, and its absence as the exception—a view of the subject which clearly proves how common he has found it. And this inference, be it observed, he draws, not from those

who had been bled, but from those treated in the ordinary way.

I cannot help thinking that the idea originated in an erroneous theory, and has since been perpetuated by that strong tendency to copy opinions and practice which is so remarkable in the history of our art. Patients having severe fibrous rheumatism were bled; some of them afterwards became affected with pericarditis; the fact of this being almost a part of rheumatic fever was not known, and some extraordinary cause being thought necessary to account for the phenomenon, the blame was charged upon the depletion. But again, the pericarditis not being recognised as one in the train of phenomena in acute rheumatism, was supposed to be a transference of the disease from the external parts to an internal organ—a metastasis, in short; and then, by a natural train of reasoning, those causes, which experience had shewn to lead to other kinds of *metastases*, were assumed to operate similarly here. I believe that this view of the pathology of the affection of the heart which takes place in rheumatism, will be found to pervade the writings of all those who hold that blood-letting in rheumatic fever tends to produce pericarditis. Thus Dr. Alison, in his *History of Physic*, published in the fourth volume of the *Cyclopædia of Practical Medicine*, says he has no difficulty “in stating his conviction, that large and repeated bleedings in the beginning of rheumatism, increase the risk of this *metastasis*.” No ground, however, is assigned for this conviction; and it would clearly require, in order to prove its accuracy, a great number of comparative trials, made in cases as much alike as possible. Thus I have above stated, that, so far as my experience goes, the complication of the heart affection is more apt to occur in severe than in slighter cases; but it is in such severe cases that we most usually abstract blood; and then those who enter upon the subject with preconceived opinions, almost unconsciously dwell upon the depletion, and forget the acuteness of the disease which called for it, when they are seeking out for the causes of pericarditis.

If there be one class of patients more than another in whom blood-letting is comparatively seldom adopted in acute rheumatism, it is children; and what is the fact with regard to *their* liability to heart affections? Are they proportionally more or less obnoxious to this disease? I have no hesitation in affirming, that I have met with more cases, proportionally, in which rheumatic fever had led to disease of the heart in children than in adults. This remark is also in keeping with the experience of Dr. Watson, who says, that

although blood-letting does not cause any predisposition to the cardiac affection, yet that youth certainly does; and farther, that the younger the child is, the more likely is rheumatic pericarditis to supervene. Now, agreeing as I do with Dr. Watson in the statement of the fact, I venture to ask, with regard to its cause, whether this may not consist in that the younger the patient, the less likely is the necessary depletion to have been had recourse to?

Lastly, as regards this part of the question, let us observe the treatment. A patient has rheumatism of the limbs, and it is assumed, that to bleed him increases the risk of his heart becoming affected. But if the heart does become implicated, although the rheumatism still remains in the limbs, we are then told to bleed (moderately it may be, but still to bleed), by the very same parties who hold that to bleed in rheumatism increases the risk of the heart becoming affected! But if bleeding originally transferred a portion of the rheumatic action to the heart, surely bleeding farther must be attended with the risk of transmitting any portion of the disease which yet remains in the limbs, to that organ whose liability to it was first begotten by the depletion.

That blood-letting carried too far, in rheumatism, is productive of certain other injurious consequences, I feel persuaded; but nothing I have seen would lead me to enumerate pericarditis among those evils; and this, I may add, is an opinion forced upon me in the wards of St. George's Hospital, in opposition to the opinions I had previously derived from reading.

The symptoms which mark an attack of rheumatic inflammation of the heart may be divided into those immediately connected with the organ itself, and those manifested by other parts; or, in other words, into the local and general phenomena.

Of the *local* symptoms, that most commonly complained of is pain; yet there is perhaps none to which it would be more fallacious to trust, because it is sometimes entirely absent even in the most formidable cases. When present, the nature of the pain differs at different times. In one it is an acute stitch, aggravated by inspiration, and resembling that of pleurisy; in another it is a dull, heavy, burning uneasiness; but more generally it is of a character intermediate between these—that is to say, the pain is rather acute, but neither so sharp, nor so much aggravated by inspiration, as it is in pleuritis. The pain is distinctly, and sometimes very severely, aggravated by pressure; and may even be thus excited when not otherwise present. To ascertain this, the fingers must

be applied between the ribs, over the region of the heart; or the hand may be applied to the epigastrium, and pressure made upwards, inclining to the left. It will frequently be found that pain is experienced when either of these expedients is had recourse to, even although no uneasiness in the region of the heart has been previously complained of, or at least none of a more palpable nature than oppression and discomfort. Such examinations, it is to be observed, require to be made with a certain degree of caution, otherwise unnecessary pain, if not more important injury, may be inflicted.

In recent and acute cases the pain is generally limited to the region of the inflamed part; but in those who have suffered from similar attacks before, and in whom the heart has become organically diseased, the pain is apt to pervade the left side of the chest generally, and even to extend to the scapula, shoulder, or arm.

The extent to which the heart's action is altered, as indicated by the presence of palpitation, or of any peculiar affection of the pulse, is much less than we should *a priori* have anticipated, or than is often represented in books. Limiting, for the present, the term palpitation to that tumultuous action of the heart which directs the patient's attention to it, and induces him to make it the subject of complaint, I am quite satisfied that it is frequently entirely absent; while, with respect to the pulse, it not only has nothing which can be regarded as pathognomonic, but I should even say that it has no character which is calculated to afford us any material assistance in the diagnosis. Generally, indeed, it is increased in frequency (beating from 100 to 120,) and at the onset is also, I think, usually more jerking than natural; but this latter character often very speedily subsides, and then, although generally retaining its augmented frequency, it may become weak, unequal, or intermitting—all which phenomena, it is well known, may attend other diseases of the chest, more especially those attended with effusions.

But although, as I have said, the heart's action is not so often changed in rheumatic carditis as to excite a form of palpitation, of which the patient complains—as he does in various other affections of that organ—yet I believe there is no instance in the whole range of disease in which so great assistance is derived by an educated ear from listening to its sounds. Now the abnormal sounds met with in rheumatism of the heart are chiefly two; one of which conveys the idea of rubbing or friction, and the other that of blowing or whizzing. The former

of these seems to depend upon increased friction between the surfaces of the pericardium; the latter, upon increased friction of the blood as it passes through the internal apertures of the heart.

The rubbing sound conveys the idea of two surfaces moving over each other; and its occurrence, which is characteristic of pericarditis, has been attributed by some to the membrane becoming dry under the inflammatory action; by others, to the surfaces becoming rough. The latter appears to me the more probable explanation, because we have no evidence of the degree of dryness which is here assumed ever really taking place; while we have proof positive of the surfaces becoming rough, and that to an extent which there is no difficulty in believing to be capable of emitting sound. But as the inflammation must be fully established to produce the rubbing sound, so, though one of the most certain, it is not always the earliest among the symptoms. In more than one case I have suspected very strongly that pericarditis had supervened before there has been any change of sound (sufficiently distinct at least *for me* to appreciate,) and within twelve or twenty-four hours afterwards the rubbing sound has been evident. The nature of this sound is, I think, sufficiently expressed by the term I have employed, and which is that now generally adopted. A rubbing sound may also occasionally, though I believe it very rarely, does accompany the act of respiration; this, however, can scarcely be confounded with that dependent upon the action of the heart.

But as the sound in pericarditis depends upon a cause which is transient, so is it one which does not endure beyond a very limited period; for if either the opposing sides of the pericardium become coherent, or if they be farther separated by the effusion, then, in either case, the attrition ceasing, the sounds are no longer emitted, although the inflammation may still hold on its course. And again, if the disease be overcome, the lymph may be absorbed, and thus the cause of the rubbing sound will equally be removed.

Distinct and unequivocal as this sound occasionally is, yet in other cases, which nevertheless were certainly pericarditis, I have not been able to detect it, neither have those who will sometimes hear a sound so fine

“That nothing lives 'twixt it and silence.”

Were it worth while to speculate on the cause of our being thus occasionally baffled, we might presume that it depends upon some modification in the extent or nature of the effusion.

But there is also another circumstance which operates in producing this negative result; I mean, that we generally have a sound which is louder, more persistent, and more familiar to us, by which the rubbing is masked, and our attention arrested. This is the *blowing* sound in one or other of its numerous degrees and modifications. In many cases it may be heard all over the region of the heart, but is usually most distinct at points corresponding to the aortic and to the auriculo-ventricular valves of the left side: that is to say, that where the relative situation of the parts is not changed by previous disease, the blowing sound will generally be best heard by placing the ear or the end of the stethoscope at the lower part and towards the left side of the third bone of the sternum for the aortic, and a little further to the left for the mitral valves.

Where the "blowing" is heard with the first sound of the heart, and where it is perceived on placing the instrument over the carotid arteries, it is reasonable to conjecture that it depends upon disease having produced, in the aortic valves, certain changes which cause obstruction to the free exit of the blood from the ventricle. If the blowing be contemporaneous with the second sound, and not heard over the carotids, it probably will be found to depend on disease at the orifice between the left auricle and ventricle. Frequently a whizzing sound is heard with both actions of the heart, depending, in general, upon the aortic and mitral valves being both implicated in the disease. The degree to which the blowing sound is present varies much in different instances; but in well-marked rheumatism of the heart, it is rarely, if ever, wholly absent. Its general character, where the valves have not been previously damaged so as to admit of regurgitation, is that of a simple bellows sound; but sometimes it assumes a harsher character, and sometimes a distinctly musical tone. I have heard a clear musical whistle nearly from the onset of an attack of rheumatic carditis, diminishing in loudness as the disease was overcome, and passing into a simple bellows sound, which remained permanent. Indeed, there can be no doubt but that this abnormal sound may entirely cease in recent cases, the causes on which it depends being, it is to be presumed, wholly removed; but in older cases, and especially in those where the heart affection has not been early and vigorously met, the sounds alluded to are permanently present, affording every variety of intensity and tone, and too often resisting every method hitherto attempted for their removal—a

circumstance obviously depending upon irremedial structural changes having been produced: and this leads me to remark, that it is of great importance, in cases of acute rheumatism, to ascertain, at the earliest possible period, the condition of the heart, that we may not confound the phenomena produced by the attack then present with those resulting from previous organic change.

Another phenomenon connected with sound, which is sometimes, though not so generally, present in the first attack of rheumatism of the heart, is the extent to which the cardiac region becomes dull on percussion. In the normal condition the dullness extends over an inch and a half, or two inches square, the lung encroaching on the rest of the surface. But in disease the lungs frequently leave a much larger space over which they do not pass, and consequently the percussion is dull over a corresponding extent. Where this dullness comes on during acute rheumatism of the heart, it may reasonably be attributed to effusion into the pericardium. If the dullness over an increased extent depend upon enlargement of the heart, this will generally be found to have resulted from previous attacks of rheumatism, and scarcely affords any facility in detecting pericarditis, unless, indeed, by giving a larger surface over which the rubbing sound may be heard. If the dullness depend upon effusion, this will rarely assist us in originally detecting pericarditis, although it affords us a means of determining the extent to which such effusion has proceeded, and also whether the disease is on the increase or decrease. It does not usually assist us in detecting the pericarditis, because, before the effusion can have proceeded so far as to produce an unequivocal augmentation in the surface over which the sound is dull, the disease in all probability will have sufficiently manifested itself by other signs. And again, in that form of pericarditis which attends acute rheumatism, the effusion is most frequently chiefly composed of lymph, which, though it may be in quantity sufficient to produce embarrassment in the action of the heart, yet the mere increase of bulk thus produced is not usually to such an extent as to be satisfactorily judged of by percussion. A much more appreciable, and therefore more generally useful sign, in reference to sound afforded by the effusion which takes place into the pericardium in rheumatism, is the sound of the heart itself being observed to become progressively more feeble and more distant, while the general symptoms show that this is not dependent upon mere sinking. It is proper, however, to remark, in

connexion with dulness in the region of the heart, whether from its increased bulk or from effusion into the pericardium, that either may be masked by an emphysematous portion of lung interposing.

Of the *general* symptoms which indicate that the heart has become implicated in an attack of acute rheumatism, the most striking is the aspect of the patient. I venture to say there is no observant physician who has not had occasion, on going into the wards of an hospital, to stop at once on coming to a rheumatic patient whom he may have seen the day before apparently going on well, and proceed to examine the heart with the conviction in his mind, before he has asked a single question or applied his stethoscope, that carditis has supervened in the interval. This is one of the many instances in which the eye can detect what the pen cannot express. The system has taken the alarm at the new inroad of the malady; the consequent distress is depicted in the countenance, and told in every attitude and every movement. The expression is anxious; the breathing rather shallow; occasionally there is cough. The patient is sometimes very restless, but more generally lies on the back, or right side; at least it is rare to see him choosing the left. Here we have intense fever, but for the most part without the restlessness and tossing which usually attend that state. Indeed there is occasionally a fixedness in the general aspect—I had almost said in the deportment of the patient, quite remarkable; he becomes, as it were, passive, and while the immobility with which he retains one position would lead us to suppose that any other would be intolerable to him, yet I have known such a patient, upon being moved, remain in his new position apparently as determinedly as he had previously done in the other. Although, therefore, reclining on the back, or a little to the right, be the most common, and therefore, we must presume, generally the easiest posture, yet the unwillingness to move, even to resume this attitude, probably depends upon the effect produced by motion of any kind on the heart's action, which thus becomes for the time still farther embarrassed. In the cases where this unwillingness to any change of posture is most marked, the action of the heart is usually feeble and the sounds indistinct. Dr. Latham, who has excellently described this phenomenon, attributes it, and probably with justice, to the presence of fluid effusion in the pericardium. And here I may observe that where copious effusion takes place rather rapidly into the pericardium, unaccompanied by hydrothorax, the patient will sometimes prefer to lie perfectly

flat on the back, without having the shoulders raised at all, being just the reverse of what we are almost invariably taught in books. Such, at least, has been the fact in several cases in which I had an opportunity of examining the bodies after death, and in others where the patients recovered, after having had symptoms which led me to believe that there had been fluid in the pericardium.

When the peculiar anxiety of countenance above-mentioned, and the reluctance to change of posture, are most marked, there also will be frequently seen a disposition to syncope. I say a *disposition* to this state, because I think the patient very rarely does actually faint. The pulse, too, becomes unsteady, and varies in the character of its beats, but rarely has any considerable power. There is heat of skin, and thirst, and furred tongue, and sluggish bowels, and high-coloured urine, and all the usual symptoms of inflammatory fever.

Now when either all, or several of the phenomena above described, occur in the course of a case of acute rheumatism, there can scarcely be any difficulty in detecting the nature of the complication which has added to the severity of the primary attack; there can scarcely be room for hesitation in declaring pericarditis to be present.

But there is one very peculiar train of phenomena which may tend to divert the attention of the practitioner from the real seat of mischief, and which requires an especial notice.

ON THE

ACOUSTIC PRINCIPLES OF THE STETHOSCOPE.

By CHARLES COWAN, M.D. E. & P.

Physician to the Reading Dispensary.

To the Editor of the Medical Gazette.

SIR,

WE were much interested by an ingenious paper of Dr. Budd's on the acoustic principles of the stethoscope, inserted in the No. of your valuable journal, for May 29, 1837. We had long felt dissatisfied with the generally received explanation of how the stethoscope transmitted the sounds from the chest to the ear, and suspected that too much importance was attributed to the form of that instrument—to the shape of its internal surface, and to the conducting power of the column of air which it incloses.

Dr. Budd's observations confirmed this impression, and though not demonstrative of the fact, seemed almost to prove that the *solid material*, and not the *air*, was at least the principal medium of communication. The following week your column contained a strong stricture by Dr. Williams on the views entertained by Dr. B., and the latter not having since replied, we beg leave again to agitate the question; and we think that we shall be able to show that Dr. Williams's explanation is not "the only one consistent with the phenomena of auscultation and the laws of acoustics."

Dr. W. commences his communication by expressing "his jealousy of the attempts of those who, labouring in the same field, evince an imperfect knowledge of the science, or want of experience in the art," and seems almost to consider it a matter of course, that those who venture to differ from himself are *de facto* in the wrong; quoting long and numerous extracts from his writings to prove his prior acquaintance with whatever there may be of truth in Dr. Budd's opinions, and terminating by asserting that the latter is in error wherever he is original. Throughout Dr. Williams' remarks there is a tone of authority, a monopolizing of truth, as it were, and an anxiety to preserve favourite opinions from foreign aggression, which in subjects open to discussion had better be avoided; but which at the same time we doubt not are more apparent than real, and may fairly be attributed to the strength of his conviction, and to the intense interest which he has always taken in the subject. We think also that Dr. Budd's merit as an investigator has been underrated, and that the facts which he adduces in support of his hypothesis have not been fairly examined or satisfactorily answered. In the following observations we shall venture to advance some additional objections to the views of Dr. Williams, which he has so long and so ably promulgated; or rather we shall endeavour to strengthen the theory maintained by Dr. Budd.

There is great praise due to Dr. Williams for having so strongly insisted upon the importance of the principle, that sound is best conducted by media of analogous density to the vibrating body, and that although as a general fact the conducting power is in propor-

tion to the density, yet the influence of the condition we have just alluded to is such as frequently to falsify a rule which we have been in the habit of regarding as universally applicable.

The reason why substances of light and elastic texture, such as wood, are better adapted for stethoscopes, is simply because their density approximates more closely to that of the thoracic parietes, and not because they are absolutely the best conductors of sounds. Experience proves that metals and the denser woods are inferior to deal or cedar, when employed in the transmission of vibrations originating within the chest; and experience also proves that a hollow cylinder possesses some advantages over a solid one.

So far, then, no difference of opinion prevails; but we would ask, what application does Dr. Williams make of the principle on which he so strongly insists? The solid part of the instrument, he says, is to transmit the sounds originating in the *dense contents* of the chest, while the air conveys the sounds originating in the *more aerial contents*. "To concentrate the diffused sound of respiration," he continues, "and to expedite the examination by making the stethoscope take in as large an extent of surface at a time as possible, the cylinder is hollowed at the pectoral end into a conical cavity, the apex of which terminates in a central canal; so that all vibrations communicated to the air in this cavity are concentrated into the canal and conveyed to the ear."

Now it is undeniable, that whatever may be the source of vibrations in the interior of the thorax, their sensible effects can only be conveyed to the ear through the secondary vibrations of the parietes, which are more or less strongly agitated as the source of the internal sound originates in a rarer or denser medium. No distinction can therefore be founded upon the different nature of the sounds, as to their origin, because they must all be transmitted to one common medium, and having once caused the latter to vibrate, their further propagation can no longer be facilitated by being again made aeriform. If the vibrations from within are too feeble to act on the parietes, they are, by a stronger necessity, too feeble to produce aeriform vibrations external to the chest; but however slight the vibrations of the parietes may be, is it not far more con-

sistent with theory to admit that they would be best transmitted by a solid of more or less analogous density, than that they should react upon so rare a medium as the air, which must, from the law already laid down, be under such circumstances much less easily impressed? We cannot auscultate the aerial contents of the chest themselves, as Dr. Williams' supposition would require, but are wholly limited to the examination of their effects on the walls of the thorax, and we again say, that as the vibrating surface is always a solid one, whatever may be the source of sound, (whether the distension of the cells by air, or the rushing of blood through the cardiac cavities,) yet having once caused the thorax to vibrate, it must be far more easily conveyed to the ear by a solid than by an aeriform conductor. To suppose the reverse is to unsettle the very law which Dr. Williams is so anxious to establish.

Theory, therefore, is strongly in favour of the inference, that the stethoscope is essentially a solid conductor, under all circumstances.

Let us now turn to experiments.

The two observations on which Dr. Budd principally founds his opinion, are the facts of the respiratory sounds being inaudible, if the slightest interval exists between the ear or thorax and the stethoscope; concluding that so small an interruption to the continuity of the tube would not materially interfere with the aeriform vibrations, were they the means of transmission of the sounds. In reply to this, Dr. Williams justly observes, that the conducting power of air is immensely impaired by divergent vibrations; and we have also satisfied ourselves of this fact by direct experiment. Indeed, if we recollect the reflections of sound which take place in a tube, more particularly if evaded at one end, as is the stethoscope, we can easily understand why the slightest interruption to the continuity should greatly interfere; for all the lateral vibrations would pass off from the open extremity in the direction of their last reflection, and never enter the ear at all.

We freely admit that these experiments are by no means satisfactory, nor are they irreconcilable with the views entertained by Dr. W.; who continues—"Now the stethoscope is also a closed tube, in which all lateral divergence is prevented, and the air within it there-

fore forms an elastic conductor, which transmits from end to end the slightest vibrations; being, as I have before observed, the best conductor for sounds produced in air;" and immediately above he cites in illustration of this, the experiment of M. Biot, in which that observer found that the slightest whisper could be distinctly heard through 3120 feet of iron pipe. And from the differing rapidity of the sound when produced by striking the pipe, from what depended on the voice, he distinctly proved that air was the conducting medium of the latter. The whisper was here heard by the conducting power of the air, and not of the solid, because the medium first impressed was similar in density and continuous with the contents of the pipe. The sound therefore necessarily travelled in that direction. But the stethoscope reposes on a vibrating solid, which transmits its vibrations to the solid material of the instrument in preference to the air, on the same principle as a blow at one end of the pipe was conveyed by the pipe itself, and not by its aeriform contents. Admitting the sounds in the chest to be produced in air, they are not heard by the air, from the simple fact, that no direct communication with the exterior takes place. Had the end of the pipe been closed by a solid continuous with the tube, the result would have been very different, and the parietes of the tube have been the conductor of the vocal vibrations to the ear, if in contact with the other extremity. These are really the conditions of the stethoscope when applied to the chest. The sounds are interrupted by interrupting the contact of the ear or chest with the instrument, because we then interpose a layer of air, which, from its comparative rarity, becomes a very imperfect conductor; while, on the other hand, we re-establish the sound in proportion as we renew the contact with the thorax by bodies of density similar to the texture of the stethoscope itself. In either case, then, ceasing the contact of the stethoscope with the chest or ear must materially interrupt the sound.

Every one is perfectly aware that the respiratory murmur is heard very distinctly through a solid cylinder of wood; through a tube filled with water; but at the same time it is generally admitted that the hollow cylinder possesses certain advantages. Dr. Williams

asserts that if the stethoscope conducts sounds merely as a solid, the central perforation can be of no use. Now this does not at all follow, since by perforating the stethoscope you diminish its bulk and its inertia; you double its surfaces; you modify the amount of its contact with the vibrating body; and render it more easily impressed with feeble vibrations. "*Thinning* a sonorous solid increases the sphere of its vibrations, and *lightness of mass* renders them more excursive," as Dr. W. himself admits: on what principle, then, does he maintain that if air is not the conductor, hollowing the stethoscope *can* be of no use? This savours of prejudice. By lightening the mass we render it more susceptible to slighter causes of vibration, and we can thus explain why this form of instrument is best adapted for conducting the respiratory murmur and vocal resonance, and why a more solid form answers best for more powerful impressions. But to come to more direct proofs. Dr. W. declares "that if in *any kind* of stethoscope we close this tube at either end with a cork, we *vastly* impair the power of the instrument to transmit the sounds of respiration, and of the voice." We have made numerous and careful experiments upon this point, assisted by a pupil, who has also verified every result; and our conclusions are distinctly at variance with the assertion of Dr. W. We will now briefly refer to some of the principal results.

1st. If one or both ends of the stethoscope are accurately closed with cork*, the respiratory murmur is only *very slightly* weakened, and the instrument would still suffice for every practical purpose.

2d.—If the interval between the corks be filled with water, the sounds appeared rather louder and sharper than when the instrument was unclosed.

3d.—If the cone be filled with soft cotton, and the ear end plugged with the same material, the difference in the respiratory murmur was barely appreciable.

* Two stethoscopes were used of exactly similar structure, for the purpose of more rapid comparison. Each experiment was also frequently repeated, to avoid any deception which accidental changes in the intensity of the respiratory murmur might produce; and having for some years devoted much time and attention to auscultation and percussion, some confidence may be placed in our power of appreciating the varieties in the character of thoracic sounds.

4th.—The tube was successively obstructed with dough, wax, paper, at one or both extremities; the only appreciable result was a certain diminution of the sounds, but never to such an extent as to make them not easily heard, or to neutralize the indications of the instrument.

5th.—A tin tube of an inch and a half in diameter, eighteen inches long, and closed at both ends by the same material, allowed the respiratory murmur to be very distinctly heard. Firmly grasping the tube with the hand, very sensibly impaired the conducting power. This was only slightly the case with the stethoscope.

6th.—When the cavity was obstructed by a silk handkerchief, it produced very little, if any, difference in the sounds; filling the tube with water considerably diminished its conducting power. Leaving the extremity of the tube next to the chest open, seemed rather to diminish than increase the sounds.

In all cases accurate contact of the conducting medium with the chest and ear was indispensable. The vocal vibrations were evidently louder and more defined, through the stethoscope closed at both ends and filled with water, than when open.

The advantages of the perforated stethoscope, when listening to sounds produced in air continuous with that in the tube, were very evident.

If an individual spoke, or gently breathed through a stethoscope, and with another applied to the ear we listened at a short distance, avoiding touching, the difference in the sound when the stethoscope was free or obstructed, was at once palpable and considerable. If we applied a large glass receiver of three inches in diameter to the chest, and attentively listened at a short distance from the open but contracted end, a distant feeble murmur could be detected, which was only slightly increased by the contact of the ear with the glass. If a stethoscope was introduced through the neck of the receiver, and all contact avoided with the glass or thorax, the ear could plainly perceive a feeble respiratory murmur, which did not vary by moving the instrument nearer to or further from the chest, but which *wholly ceased* when the tube was obstructed by cork or wool. The only difference in this case, from listening to the thorax with the stetho-

scope at a distance from the parietes, was the presence of the receiver, which became an extensive vibrating surface, and capable of communicating sensible agitation to the air it inclosed; exactly as the tuning key impresses the surrounding air with sensible vibrations when in contact with an extensive surface of wood. These experiments sufficiently prove the necessity of the tube being free when conducting aeriform vibrations. Perforating a tube, as Dr. Williams observes, very materially interrupts its conducting power. But this may be explained by the injury sustained by the fibres which are intersected, and the unfavourable condition of the tube as a whole; on the same principle, that a slight crack interferes with the vibrations of a cup or glass. It may also depend (and perhaps this is the true reason) on the numerous echoes of external vibrations in the tube; and at all events is not demonstrative of the conducting power of the contained air, in the way Dr. W. would suppose.

It may still be objected, that if the solid material of the stethoscope is the conducting medium, the vibrations must ultimately be transmitted to the air in the external meatus, and that the difficulty involved in a change of medium still remains. Dr. Budd supposes that the solid portions of the auditory apparatus convey the sounds, but this strikes Dr. Williams as so absurd, that he says, p. 351, "Nay, according to Dr. Budd, these sounds being transmitted to the organ of hearing, not through the air in the external meatus, but through the cartilages, they should be heard as well with the ear closed or stuffed with any dense matter." Now we hope Dr. W. will not turn a deaf ear to us when we assert that this is actually the case. The ear, when stuffed with cotton, and when insensible to the majority of sounds around, gave no evidence of any obstruction when applied to the stethoscope with the tube either open or closed. We seemed scarcely aware that the meatus was obstructed so long as we remained in contact with the instrument, but the moment that we listened to sounds taking place around us, the confusion and indistinctness were painfully evident. My pupil, in his zeal, introduced a piece of cork, which fitted closely, into the meatus, covering it with cotton, and

the whole with a layer of putty; and he was not sensible of any increased difficulty of hearing the respiratory murmur. When both ears were obstructed, the same results were obtained. Every one admits, that where it can be applied, the respiration is as distinctly heard by immediate as by mediate auscultation; which certainly ought not to be the case if the stethoscope concentrated the sound in the way in which Dr. Williams supposes.

We may also mention that a recent German writer has made some very interesting experiments upon the auditory functions, plainly proving that a great many sounds are transmitted through the solids of the body, and not by aeriform vibrations; and he considers that the cochlea is the particular seat of these sounds, in consequence of the direct contact of the nerve with the solid lamella of bone which that portion of the ear contains.

The circumstance referred to by Dr. Budd, that individuals who are deaf from diseases of the tympanum are sensible to sounds conveyed through a solid in contact with the cartilages of the ear, may also be again mentioned.

From all these facts and considerations, we feel justified in concluding that the stethoscope acts almost entirely as a solid conductor, under all circumstances, in reference to the sounds within the chest, and that the column of air which it incloses exerts little, if any, influence upon its efficiency as a conducting medium;—that the superiority of a perforated cylinder over a close one, simply depends upon the former being more susceptible, by its form and lightness, of transmitting vibrations too feeble to affect a more solid instrument; but that the benefit obtained has been greatly overrated, and the explanation hitherto given erroneous.

We are inclined to believe, that the best form for a stethoscope would be a simple cylinder of light wood, about an inch and a half in diameter, and a tenth of an inch in thickness, carefully closed at both ends by a layer of the same wood, and of the same thickness. The exact length is of secondary importance.

This would combine lightness and uniformity of material, a vibrating surface in contact with similar media on both sides, and great simplicity of structure. It is a point for consideration,

how far the portion of the thorax corresponding to the stethoscope is better situated for transmitting the vibrations from beneath, when only in contact by its circumference, or when compressed by a uniform flat surface. We cannot at present satisfactorily determine this. The effect of putting the stopper into the instrument is merely to diminish its vibrating power, and increase its connexion with the chest.

The power of more distinctly localizing certain sounds, under these circumstances, may be accounted for by its less easily transmitting the vibrations produced in the vicinity of the exciting cause.

In conclusion, we would remark, that we have not stepped forward in the character of a discoverer, but simply in support of the conclusions entertained by Dr. Budd. We think the facts now adduced less problematical than those on which that gentleman has formed his opinions; and we cannot see how they can possibly be reconciled with the theory so ingeniously defended by Dr. Williams, and hitherto so universally received. Though differing from the last-named individual on the present occasion, we are not insensible to his great merit as an accurate and sagacious observer; and while we refuse to submit to his authority, we willingly seize the present opportunity to thank him for the benefit we have often derived from his instructions.

Hoping that you will give these observations a place in your valuable journal, we remain, sir,

Your obedient servant,

CHARLES COWAN.

Reading, Sept. 23, 1837.

ON SCURVY.

From the Annual Report of

DR. MURRAY,

Principal Medical Officer at the Cape of Good Hope, for 1836.

Communicated by Sir James McGrigor, Bart.

[Continued from p. 945 of last vol.]

Report of Assistant-Surgeon Ford,
continued.

It certainly appears very remarkable, that the men of the 75th regiment should have suffered so much from scurvy, at all the posts occupied by them in the (late) New Province; and that it should

have affected them in a manner that may be considered endemial, when those of another corps (72d,) stationed in the same province, and under exactly similar circumstances, should have wholly escaped it at two of the posts, (Forts Murray and Beresford,) and resisted its influence for a considerable time at the third (Fort Cox,) which I have already stated was particularly exposed to cold and vicissitudes of climate; and when the disease did, at length, appear in this detachment, it was to a very limited extent. It must be stated, however, that the men of the 72nd regiment were relieved and moved to Graham's Town from the New Province in the end of October, about two months after the scurvy had shewn itself among them.

Within the colonial and neutral-ground border, (*i. e.* to the west of the Keiskama River,) although men of other corps, *viz.* of the 27th, 72nd, and Hottentot cavalry and infantry, were encamped or hutted in precisely the same way as those of the 75th regiment in the New Province, had similar duties, worse water, and were not better supplied with vegetables, (except at Fort Wiltshire,) only a few sporadic cases occurred: why, therefore, the 75th regiment should have been so obnoxious to its invasion, and suffered so severely from its effects, is to me, I confess, unintelligible.

I have not heard of a single instance of scorbutic diathesis having been elicited among the coloured natives; and from the inquiries I have made, I should imagine the disease to be unknown to them. It may, then, with reason be inquired, to what their immunity is to be attributed; exposed as they peculiarly are, to the vicissitudes of the climate, and to cold and moisture, from their almost total want of clothing, imperfect housing, and general habits.

In the first place, I conceive, that being trained from early infancy to endure the change of seasons and of weather without clothing, habit enables them to resist external influences, and renders their system insensible to, or insusceptible of, effects from those sources which to civilized man would be productive of most serious evils. The Caffre appears to be equally insensible to the sun's intensest rays, to nipping frosts, to piercing winds, and to winter rains; he neither diminishes nor increases his clothing to meet any of these changes; and

yet we find that he is less subject to diseases depending upon exposure to them, than man in the civilized state, who takes much care to provide against their influence.

Secondly, these people being essentially pastoral, are by nature and education addicted to active and exhilarating occupations, in which the mind and body are both engaged, such as—the chase, herding their cattle, dancing, and endeavouring by forays, conducted with activity and craftiness, to increase their means, form their chief pursuits; and few if any of them, I should say, are troubled with *emui*.

Thirdly, their general habits of temperance, and the nature and qualities of their diet, form not the least powerful preventive to the disease under consideration. Animal food forms but an occasional and small portion of their aliment; farinaceous and other vegetable substances, such as Indian and Caffer corn, pumpkins, melons, some indigenous wild fruits and esculent roots, with honey and sour milk, which are all essentially antiscorbutic, being their usual food.

The same may be said of the Hottentots, who are also inured from earliest life to atmospheric vicissitudes, to which their nomadic life exposes them; and although they are usually denominated an indolent race, I think that this character refers to them more particularly when constrained to perform services in civilized life. They are not fond of confinement, or regular routine of duty; but in their attachment to hunting, play, dancing, singing, and wandering from place to place, they evince a disposition and fondness for varied occupations.

Those Hottentots who were employed as soldiers, and who did duty in the New Province along with the 75th regiment, when scurvy prevailed there, had warmer clothing, and better lodging, than most of them had been accustomed to; and their practice of keeping fires on their floors within their huts, (as the Caffers also do,) no doubt counteracted the effects of dampness. They had the same rations as the European soldiers; and their knowledge of indigenous roots and herbs supplied them with additional vegetable aliment.

At this post, (Fort Wiltshire,) separated from the New Province only by the Keiskama River, and only 18 miles distant from Fort White, where scurvy

prevailed, the malady never broke out, and this exemption may be fairly imputed to the combination of preventive means enjoyed by the men composing the garrison. These were—the barrack comforts of substantial houses; bedsteads and bedding; the regular supply of good wholesome rations of bread or biscuit and fresh meat; a tolerable supply of vegetables; facilities of procuring additional dietary luxuries, of which the men availed themselves; attention to cleanliness; no over fatiguing duty; and amusing sports.

Two cases of the disease do appear in my return as having occurred here, viz. in men of the 27th regiment; these, however, were of a doubtful nature, the only symptom being an unhealthy state of the gums, (perhaps habitual to them,) rendering them more easily made to bleed than natural. Having detected these at inspection, and dreading the occurrence of scurvy among the men under my charge, I ordered them at once into hospital; where being detained, the one for eight, the other for sixteen days under observation, (with only a few saline aperients, and a daily allowance of vinegar, as remedial agents) I was satisfied that the state of their gums did not arise from actual scurvy, and discharged them.

I may further remark, that several men of different corps underwent solitary confinement in the cells at this post, for periods varying from twenty to forty days during the time of the prevalence of scurvy in the New Province, not one of whom shewed the least symptom of the disease.

Numerous theories and hypotheses as to the proximate cause of scorbutus have been advanced, which are important to be considered, as being the foundation upon which the different modes and indications of treatment have been constructed. The chief points of controversy have been, whether the disease is to be attributed to a primary deranged and faulty state of the fluids, and of the blood especially, or to a morbid condition essentially pertaining to the solids; but by far the greater number of physiologists and physicians are in favour of the former.

Admitting the proximate cause to consist in a morbid change in the condition of the blood, it would not be difficult to account for the atonic or asthenic state of the solids. The primary

tissues, particularly the muscular fibres, being in great part made up of the fibrine of the blood, if this fluid be vitiated, it is evident that the muscles must also become affected; and that the fleshy fibres will become weak, lax, and flaccid. In the combination of both these states, it is probable that the true nature of the disease consists; and thus the more prominent symptoms of ecchymosis and tendency to hæmorrhage may be accounted for.

As to the nature of the deteriorated condition of the blood, there are also different opinions. Cullen maintained that it consisted in too great retention of saline particles in the circulating mass, and explained this to be the consequence of interrupted secretion. Stevens, on the other hand, from experiments which he adduces as proof, insists that the black colour of the blood is owing to a *deficiency* of its saline compounds. Others explain it to arise from a deficiency of oxygen; or a diminished coherence of its molecules;—or the absorption of crude ill-digested chyle, &c.

The most important result of these hypotheses is, the influence they have had over the principles of treatment. Hence we find acids and fermented liquors extolled by one physician; substances abounding with vital air, and the inhalation of oxygen, by another; abundant supply of nutritious food with tonics, by a third; and the exhibition of saline remedies by a fourth.

The next question is—whether this disease be of a dynamic or adynamic character? On this subject I am not

quite prepared to offer an opinion, not having witnessed the disease throughout its several stages; but I am inclined to believe, that it partakes of the former in sanguine and plethoric habits, and at the commencement of the complaint, when symptoms of congestion, or increased determination to any of the viscera, probably exists; while the feelings of exhaustion, depression of energy and spirits, the bloated countenance, and ecchymosed state of the surfaces, which mark its progress, would seem to indicate its having merged into the latter.

With respect to the pathology of scurvy, as deduced from the morbid appearances observed on dissection, I am not prepared to make any remarks, never having witnessed such an investigation.

It remains for me to give some account of the cases I have had under treatment; and more particularly of such as I have conceived to be of more than usual interest.

The total number of patients I admitted under the head of SCORVUTUS during 1836, amounted to 45; among these were the two cases in the 27th regiment which I have already stated as occurring at this post; but which I now deduct, as I conceive they were not of true scorbutic character.

The remaining 43 were all received from other posts, chiefly within the New Province; and the following table will shew their relative proportion as to the number received in each month, the corps to which the men belonged, and the posts from whence they were transferred.

Corps.	Number admitted in each month.					Name of Post from whence received.						Total.
						To the Westward of Keiskamma River.			In New Province.			
	August.	September.	October.	November.	December.	Fort Wiltshire.	Double Drift.	Fort William's.	King William's Town.	Fort Cox.	Fort White.	
Sappers.....	0	0	0	2	1	0	2	0	1	0	0	3
27th Regiment..	0	0	0	1	0	0	0	1	0	0	0	1
72d Regiment ..	0	1	5	0	0	0	0	0	0	6	0	6

Total	2	3	9	18	11	0	2	1	22	14	4	34

The other scorbutic cases from King William's Town, Forts Warden, Wellington, and Waterloo, in the New Province, passed to Graham's Town and Bathurst by a different route.

The majority of these 43 men were received by me in an advanced stage of the disease, having been treated in the beginning at the posts where they became affected; others of them had not been subjected to any treatment; and some were convalescent on arrival.

The symptoms, as in other diseases, varied in different subjects, but the following were always observed in the severe cases;—fungoid and discoloured gums, with tendency to bleed; fetid breath; depression of spirits; great prostration of strength, and disinclination to move; pulse variable in frequency, but always feeble; attacks of oppressed breathing, with pain and constriction at the chest; sometimes spasmodic palpitations during sleep; tendency to syncope on sudden exertion, or exposure to cold air; extensive ecchymoses and subcutaneous discoloration on the thighs, hams, and legs; rigidity and induration of the cellular and muscular tissues, and contraction of the knee and ankle joints; sallow and bloated countenance; coldness and dryness of skin; urine scanty, and prone to rapid decomposition, with fetid odour. The state of the chylopoietic organs did not appear to be deranged, the bowels being usually regular; and although the alvine evacuations varied in appearance in different cases, they were not in any instance of unnatural or peculiarly offensive character. In one case epistaxis frequently occurred; in another, the skin was *anserine*, and had a measly appearance, with much itching; in a third, a dark, bloody fungus, called by seamen "*bullock's liver*," arose on the leg; and in a fourth, in which the right leg was considerably enlarged and ecchymosed, small pendulous bodies, resembling purple grapes, sprung from the gums.

In the treatment of all those patients I was guided by the chronic nature of their symptoms, and the evident asthenia, and general cachexy, which they presented: my practice was accordingly conducted on the tonic principle, which was chiefly fulfilled by dietetic means, combined with the use of saline remedies; and I also studied to excite a

moral influence of a cheering nature, by promoting amusing occupations, with moderate exercise.

I must remark that during the period I had the management of these cases I was not acquainted with the antiphlogistic mode of combating this malady, lately recommended; but even if I had. I much question whether I should have considered its adoption prudential in the advanced stages I found them; and whether it would have been attended with those salutary effects which it has been said to produce when employed in the early periods of the disease.

I do not wish to be considered sceptical, or prejudiced against the treatment by depletion with the lancet and purgatives: on the contrary, in the early stages of scurvy, I conceive it to be based on sound pathological reasoning, and I acquiesce in the opinion, that "the lassitude felt at the commencement of the disease arises from oppression of the nervous and vascular systems;" and when symptoms of engorgement or determination to any viscus manifest themselves at the commencement of the attack, early and judicious abstraction of blood would appear to be the means most likely to remove this oppression; but, if the disease be not arrested at this period, and by long protraction has assumed the asthenic character, the patient having become sallow, dejected, feeble, apathetic, and disease of the lymphatic system appearing to predominate, I am of opinion that this practice is contra-indicated, and that other means must be adopted to restore the vitiated condition of the blood.

For the fulfilment of this object I conceive that the removal from the locality where the disease has been contracted, together with a moderate tonic corrective and nutritious diet, and saline medicines, attention to general comfort, and promoting mental amusements and bodily exercise, are the means most to be depended upon.

In my patients the benefit derived from removal from the place of its generation, and the advantages gained by change of air, were remarkable; an evident improvement having usually been observed within a few days after their arrival at this post.

Even in the worst cases the functions

of the stomach did not appear to be in the least deranged; the appetite being unimpaired and free from caprice, and the process of digestion performed with apparent regularity and ease.

The ordinary diet allowed to each of the scorbutic patients daily, consisted of coffee, with sugar and milk, and a quarter of a pound of bread, for breakfast; half a pound of bread, half a pound of fresh meat made into soup, with fresh vegetables and rice, and salt *ad libitum*, for dinner; and boiled rice, with milk and sugar, for supper. In addition to these they got two gills of good Cape Madeira wine, or, when it was not to be had, half a gill of French brandy, with water and sugar, at their dinner; with half a gill of vinegar daily, and on every alternate day an orange, or half a lemon, as they could be procured.

In most cases the use of vegetables and sub-acid fruits moderately relaxed the bowels, and in two instances produced a slight diarrhoea; so that purgative medicines were rarely required; when an aperient was called for, $\mathfrak{z}\text{ij}$. of Epsom salts in bitter infusion, along with some cordial tincture, or given in a state of effervescence, by adding carbonate of soda and acid, answered well.

I employed gargles of solution of chloride of lime for the mouth, and friction, with oily and stimulating liniments, for the limbs.

Under the foregoing treatment, amendment and convalescence proceeded rapidly; in only two cases was recovery protracted beyond a month, and many returned to their duty in a much shorter period.

As improvement took place, the sleep became undisturbed by palpitations of the heart and oppression of breathing; the livid discoloration and indurated swelling of the limbs gradually gave way; the skin became warm and soft; the tendency to fainting ceased; the spongy condition of the gums subsided; and the spirits became cheerful. The symptoms last to disappear were pains across the loins and chest, especially the latter; and for some time after convalescence they were easily re-excited by any unusual exertion.

[To be continued.]

SOME OBSERVATIONS
ON THE
PHYSIOLOGY AND PATHOLOGY
OF THE PORTIO DURA.

To the Editor of the Medical Gazette.

SIR,

THE following case was admitted by Mr. Arnott, and fell under my care during his temporary absence. Some circumstances in it may perhaps be interesting to your readers.

Your obedient servant,

ALEXANDER SHAW,
Assistant-Surgeon, Middlesex Hospital.

Davies' Terrace, Brook-street,
Oct. 15, 1837.

*Injury of the Head, with partial
Paralysis of the Face.*

Geo. Kearsley, æt. 20, was admitted on the evening of September 3d, with a severe injury of the head, received by falling out of one of the carriages of the Birmingham Railroad, when the train was at its most rapid speed. It appears that, being intoxicated, and sitting on the end seat of an open carriage, his hat fell off. He turned sharply round to recover it, when he was suddenly thrown from the vehicle, and alighted a little way from the iron rails. When brought to the hospital he lay comatose, breathing heavily, occasionally vomiting, and when roused, he struggled and became noisy. There was an open contused wound of the scalp, near the tuberosity of the occipital bone, a little to its left. Blood flowed freely from the right ear. His head was shaved, and cold lotions applied.

Sept. 4th.--It is difficult to rouse him; the pupils contract on exposure to the light; he vomited, in the morning, a quantity of bile; his bowels have been freely evacuated by a dose of calomel and jalap, followed by a colocynth enema. He was ordered—

Calomel, gr. ij.; Antimon. Tartariz. gr. $\frac{1}{2}$, every four hours. A poultice to the wound. The cold lotions to be continued.

5th.—Having had some increased heat of skin, attended with flushing of the face, twelve leeches were applied to the head. He lies crouching in bed.

Mustard cataplasms have just been applied to the calves of his legs; and these, together with the leech-bites, appear to make him restless; nevertheless, he is difficult to rouse. The blood still oozes from the tube of his ear.

6th.—The muscles of the right side of the face (except those that move the jaw) are found to be paralysed. On a close examination, these are the only parts similarly affected. The sensibility of the side of the face is not impaired. He protruded his tongue, after much rousing. The nurse informs us that he exhibits signs of being desirous of using the close-stool, and gets out of bed for that purpose with her assistance. The bleeding from the right ear has ceased.

7th.—The symptoms are nearly the same. Although the distortion of the features is more remarkable than it was yesterday, the right eye is closed as in natural sleep; and even after the eyelid is raised, it descends again, so as to cover the eye. A considerable ecchymosis is now seen behind the ear.

The pills to be taken at intervals of six hours. A blister to be applied to the back of his neck.

11th.—As it appeared, from his frequently raising his hand to the right side of his head, that he suffered some pain at that part, six leeches were applied; and it was observed that this was followed by an improvement in the condition of his face.

The pills to be taken three times a day.

13th.—The features are now so near being equally balanced, that the distortion of the face can only be perceived with distinctness when he is roused, and uses the right side of his face.

16th.—All his symptoms are improved, but the amendment in his face has not continued. He was found at the visit with a book in his hand. For the last three days he has had a constant hacking cough, as if he were clearing off mucus from the palate. On inspecting the throat, the uvula was found to be turned obliquely to one side, so that its point was directed towards the right amygdala; yet, when he inspired, the velum was elevated on both its sides. The eyelids were observed to be closed, as before, although their margins did not quite meet; and after elevating the upper eyelid, it descended again when he was asked to wink. But it was no-

ticed that the eyelid did not descend with any degree of force; on the contrary, it presented a looseness and flaccidity which proved that the orbicularis was passive. On narrowly watching this motion, it was seen to depend, in a principal manner, upon the revolving of the globe of the eye, which takes place when we wink; for it was only after the cornea had been elevated, so as to be hid behind the raised eyelid, that the eyelid dropped over the white part of the eye.

He was ordered to use an astringent gargle, and to rub the skin behind and under the ear, twice a day, with mercurial liniment. Simple dressing to be applied to the wound, in place of the poultice. The pills to be discontinued.

23d.—He has been out of bed for some days. The eye is slightly inflamed, and he finds it weaker than the left, especially during candle-light.

A blister was ordered behind the ear.

27th.—Hitherto, owing to the general stupor with which he has been affected, it has been difficult to ascertain to what degree his hearing was injured on the right side. At one time it was our impression that the sense was entirely lost; but he now hears apparently quite well on this side, and only complains of a crackling noise in the ear.

October 6th. — When asleep, his eyelids were noticed to be perfectly closed; and he afterwards mentioned that it was without his consciousness that they were shut. A marked difference, however, is observed in their position when he is awake. A short time ago, when he lay comatose, they were always shut; and even after he recovered, the eye-lids closed when he made the attempt to wink; but now they remain wide apart, and the upper one no longer descends, even if he winks with all his force. Indeed, it appears raised to a higher level than before.

10th.—He has been made an out-patient: a second blister was lately applied behind the ear; he has also continued rubbing the cheek frequently during the day, to excite the muscles. There is a manifest improvement in the appearance of the face, but he cannot close the eye any better.

REMARKS.—The circumstance that gives the principal interest to this case, is the occurrence of partial paralysis of

the face, in connexion with concussion of the brain. Previous to our improved knowledge of the functions of the nerves, such a combination could not have been explained in any satisfactory manner. No reason could have been assigned for certain muscles of the face alone being paralysed, while others immediately adjoining those that were affected retained their power; nor could it have been understood how any of the muscles of the face should have become paralysed without the integuments being deprived of their sensibility. The only way of accounting for this kind of paralysis would have been by supposing that the injury to the brain, occasioned by the fall, had given rise to it. Yet such an explanation would only have increased the obscurity that already characterizes the symptoms resulting from blows on the head; for no lesion of the brain hitherto described has ever been found to produce a loss of power so limited in its nature as that presented in the foregoing case. When it is known, however, that each nerve to the brain is endowed with its appropriate function, it becomes an easy task to distinguish between the effects of a local injury to one of them, in its course from the brain, and the symptoms denoting a general disturbance of this important organ itself. Here, for example, no doubt can be entertained, that independently of the violence of the brain giving rise to the usual symptoms of concussion, the portio dura of the seventh pair has received an injury in some part of its course; and that this has occasioned the partial paralysis of the face. The portio dura, it has been ascertained, alone controls the particular muscles that have been paralysed; it is known, also, that in its passage through the bones of the skull, it pursues a different route from the rest of the nerves; it can easily be understood, therefore, that it alone may have been injured, while the others escaped. Such an explanation will account for the sensibility of the skin, and also for the power over the muscles of the jaws remaining unimpaired, since neither of these properties depends upon the portio dura, but they are both conferred by the fifth pair, which takes a distinct course through the bones from that nerve.

This case is a correct parallel to others that I have witnessed. Indeed, it may be stated that partial paralysis of the

face, of the same kind as was exhibited in this patient, is not an uncommon effect of injuries of the head. It is, at all events, remarkable that from such accidents the portio dura is more liable to be injured than any of the other cerebral nerves. There is evidence of this in the recorded cases of affections of the different nerves of the head. If we refer to the papers on Partial Paralysis*, by Mr. John Shaw (containing the first illustrations submitted to the profession, of the practical benefits to be derived from the discoveries in the nervous system), or to the collection of cases in Sir Charles Bell's work on the nerves†, where a most extensive series of local nervous affections from different causes is given, it will be found that a considerable number of these resulted from blows received on the head. Ten such cases, at least, may be comited. Now in all of these the portio dura was injured; and in one alone, characterized by Mr. Shaw as uncommon in its occurrence, the fifth pair was partially involved in the injury, along with this nerve. Hence it is interesting to inquire, what is remarkable in the anatomy of the portio dura, that should render it so peculiarly subject to have its function destroyed in these cases of blows upon the head. The explanation, as it appears to me, is to be sought for by attending to the course which this nerve takes through the bones of the cranium, and by bearing in mind, at the same time, the principle of *contre-coup*.

It is by a circuitous route, through a canal of some length and complexity, that the portio dura pierces the temporal bone. Now, it is at this very part of the skull that we learn, both by experience and by studying the forms of the bones on the principle referred to, that the vibrations caused by a severe blow on the head are most powerfully felt: it is here that fissures produced by injuries received at distant parts of the skull are most frequently found. We cannot be surprised, therefore, when the portio dura (which, notwithstanding its name, is extremely delicate in its texture) has to pass through the temporal bone, inclosed in a narrow canal, with boundaries of such great density,

* Quarterly Journal of Science, 1821. Medico-Chirurgical Transactions, 1822.

† Bell on the Nerves. Third edition, 1836.

that it should be peculiarly liable to have its function destroyed by the vibrations of the skull. Blows may be inflicted on the head, of every different degree of violence short of producing actual fracture of the bone, which will, at the same time, cause a considerable spurring out of the bone at the temple, and consequently a shock extending through the canal that contains the portio dura; and no one can venture to say what slight degree of concussion communicated to the nerve thus enveloped may not produce the immediate loss of its power; or by occasioning the effusion of blood, or of serum, or of lymph, around it, give rise to the subsequent destruction of its function. Just as hæmorrhage from the ear, which was one of the symptoms in this case, may either indicate a trifling laceration in the tympanum, or a fracture extending through the base, so may paralysis of the muscles of the features indicate either a slight or a formidable injury to the temporal bone. But let this opinion be correct or not, I conceive that I am borne out in saying, that the frequency with which paralysis of the face, hæmorrhage from the ear, and, I may add, effusion of blood at the temple from rupture of the meningeal artery, attend violent blows on the head, is to be accounted for by the tendency which the vibrations have, on the principle of *counter-fissure*, to be concentrated towards the temples.

Without hazarding an opinion as to the exact nature of the injury received by the nerve, in this particular instance, I may be allowed to make a few observations on the subject. When we consider the kind of accident that befell the patient, the state of insensibility in which he lay for more than a week, and that the hæmorrhage from the ear lasted even for three days, we cannot help concluding that there must have been a fracture extending across the temporal bone, lacerating the portio dura in its canal. A fissure through part of this bone might have existed, even although the symptoms were only those of concussion. Nor will the recovery of the patient be offered as an argument against this opinion. I have, in the museum of the school, two interesting specimens of skulls, exhibiting fissures (one complicated with fracture) extending into the temporal bones in both instances; the fissures approach

closely to the canal for containing the portio dura; yet it is obvious, from the signs of reparation, that the individuals from whom they were taken survived the accidents. But if there had been a fracture, in Kearsley, we should have expected to find, along with the hæmorrhage from the ear, some puffiness or discolouration of the integument at the temple. It may also be argued, that had the injury to the bone been of such a severe nature, the paralysis would have immediately succeeded the accident, instead of appearing, for the first time, on the fourth day. Besides, the manifest improvement in the condition of his face, shortly after the first accession of the paralysis, is inconsistent with the idea of the nerve having been torn through. It is to be presumed, likewise, that if the bone had been fractured to any extent, the portio mollis could scarcely have escaped; yet when the patient left the hospital, his hearing was scarcely, if at all, impaired. In a case that occurred, not long ago, in the same ward where Kearsley was lying, a patient had partial paralysis of the face, similar to that with which he was affected, and produced from the same cause, a fall from a height: like him, he had also hæmorrhage from the ear corresponding with the paralysed side; this hæmorrhage continued for some days, when it was succeeded by a copious discharge of clear serum from the ear, which only ceased when the patient died, which was in the course of about ten days. It was found, upon examination, that a fissure extended across this side of the skull, towards the foramen magnum; that the dura mater had been torn where it lines the temporal bone; and that this had permitted the serum, secreted by the membranes of the brain, to distil through the crevices of the bone and escape by the external ear. The preparation of this bone which is in my possession, shows that both the portio dura and the portio mollis have been torn across in the interior of the petrous portion: and it leads us also to reflect on the improbability of these nerves ever recovering their functions after such an accident. It will, perhaps, therefore be more consistent with the facts observed in the case of Kearsley, if we consider that instead of there being a fissure extending completely through the bone, there was only, in consequence of the

shock communicated by the fall, a partial breaking up of the thin partition in the interior of the temporal bone that divides the portio dura from the cavity of the tympanum. Such a fracture would be attended with laceration of the lining membrane of the tympanum, and might have given rise to the hæmorrhage from the ear, without being sufficient of itself to disturb the functions of the portio dura, so long, especially, as the blood continued to escape from the ear. When, however, the blood ceased to flow, it is probable that it accumulated in the tympanum, coagulated and pressed upon the nerve, thereby producing the paralysis. This corresponds with the manner in which the paralysis of the muscles took place; for it did not commence till the hæmorrhage from the ear ceased; and it corresponds also with the partial recovery of the patient, for it is not unlikely that the effused blood would be gradually absorbed in part.

In the narrative, a peculiarity was noticed in the appearance of the uvula, which deserves some attention. I must state, however, that the appearance to which I refer has been observed in such a small number of cases that it is questionable whether I ought to draw any conclusions from it; but perhaps the observations I am about to make will induce others to attend to the subject. On looking into the patient's throat, and directing him to inspire, the uvula was seen to turn obliquely to that side on which the muscles of the face were paralyzed; and this appearance continued to be observed during all the time he was in the hospital. The question therefore arises—had this condition of the uvula any thing to do with the affection of the portio dura? Now this will not appear an improbable supposition, if we recollect that a branch of this nerve may be traced, if not directly to the soft palate and uvula, at least into that plexus of nerves which supplies these parts. A twig derived from the digastric branch of the portio dura joins the pharyngeal plexus; and anatomy, which is a better guide than experiment, in questions relating to the functions of nerves so deeply seated, would lead us to conclude that, as it is through this plexus that the motions of the soft palate are performed, the branch of the portio dura that assists to form it may possess

a certain influence over the muscles which move the palate*.

The fairest and most unexceptionable mode of verifying this observation will be to examine the appearance of the soft palate in numerous cases of disease affecting the portio dura, while it is still contained within the temporal bone—that is, before it has given off the digastric branch. Hitherto I have only observed a similar condition of the palate in one other case; and it was favourable for the observation, as the paralysis of the face arose obviously from the nerve being injured in its course through the temporal bone. The following is the memorandum that I made:—"On looking into his throat, and making him inspire, the uvula became corrugated, but there was an apparent distortion of the arches of the palate; they were contracted on the side corresponding with the sound side of the face, and relaxed on the other." In a thesis by M. Montault, on Hemiplegia of the Face, I find that he likewise has observed an obliquity in the arches of the palate, in a patient who had partial paralysis from disease of the portio dura; but the description that he gives of the case is not sufficiently exact to allow me to draw any conclusion from it. If future observation shall confirm the idea that I have here offered (and I beg to repeat that I propose it with considerable diffidence), that the motions of the velum palati are in some degree, for I do not suppose that they are wholly, subject to the influence of the portio dura, it may then be asked what is the meaning, in the case that I have related, of the point of the uvula having been turned towards the paralytic side? Now this is the very position which we might expect the depending part of the uvula to assume, by the contraction of the muscles of one side of the palate alone. As the levator palati draws the velum nearly directly upwards and backwards, it will not have any considerable influence upon the uvula; but as the circumflexus or

* I performed the experiment of cutting across the portio dura in a dog, with the view of ascertaining whether it would produce any effect on the motions of the palate; but I confess that I could not obtain any satisfactory result. To divide the branch that joins the pharyngeal plexus, it is necessary to cut very deeply; and the injury to the adjoining parts is consequently so extensive that no legitimate conclusion can be drawn from the experiment.

tensor palati stretches the palate laterally towards the hamular process of the sphenoid bone, round which its tendon winds, it will draw the highest part of the uvula that is attached to the centre of the velum to that side, and, by so doing, cause the point of the uvula to turn obliquely to the opposite side. In short, we may expect the same to occur with regard to the uvula that takes place in the tongue: if the muscles of one side of the tongue be paralyzed, and the patient be made to hold it out, the tip will be inclined towards the palsied side; the explanation of which is, that owing to the muscles at the root of the tongue on the sound side operating most powerfully, the root itself is drawn towards the sound side, and the point is consequently directed towards the paralytic side.

I may now be permitted to make a few remarks on the condition of the eye-lids. It was observed, for about a fortnight after there were the most unquestionable signs of the muscles of the forehead and eye-brow, as well as of the cheek, nostrils, and mouth, being paralyzed, that the patient continued to keep his eye shut, and when the eye-lid was elevated it descended again, in correspondence with the left eye. These appearances caused some who witnessed the case to surmise that the orbicularis oculi preserved its power, probably because the nerve had been only partially injured. But this opinion could not be maintained, when the loose flaccid condition of the eye-lid, as it descended to cover the eye, was observed; for it was obvious, as it has been noticed in the case, that although the lid moved, the fibres of the orbicularis did not contract. A question therefore arises, what can cause the eye-lid to close, when the muscle on which its motion directly depends is paralyzed? How does it happen that the levator palpebræ, which is the antagonist of the orbicularis, does not lift the eye-lid and keep it so elevated? Looking at the patient's countenance, we had a striking enough exemplification, in the distortion of the features, of the tendency that is common to all muscles that retain their power to drag those that are paralyzed towards them. In the case of ptosis, resulting from paralysis of the levator palpebræ, we know that the orbicularis, when it preserves its power, keeps the eye-lid incessantly closed. Is it not strange, when the circumstances are reversed,

the orbicularis being paralysed and the levator palpebræ retaining its power, that the eye-lid should still be depressed?

It may assist in solving this question, if we recollect that, during the time referred to, the patient was comatose; and accordingly there was no reason to expect that the levator palpebræ would be brought into active use. But independently of this, we have to remark that this muscle has an action of a peculiar kind, corresponding with its office, and distinguishing it from other muscles. During the third part of the twenty-four hours, while we are asleep, the levator palpebræ is constantly relaxed; and while we are awake, it relaxes, in the act of winking, about once every minute. Hence it is difficult to say whether, if left to itself—that is, if it be unopposed by other muscles—its natural condition will be to remain in a state of contraction or relaxation. In the present case, owing to the paralysis of the orbicularis and the insensibility of the patient, the levator palpebræ was in a continued state of relaxation, and the eye-lid was perfectly passive, as if both its muscles were paralyzed. We can, therefore, understand why the eye-lid fell.

But this view will not throw light upon what has been further stated in the case—that the patient, when he was so far recovered as to understand our wishes, could close the eye after the eye-lid had been previously elevated. Such an effect could not be produced in a mere passive condition of the parts. To explain how it took place, we must turn our attention from the eye-lid to the eye-ball, and observe that the action of winking does not consist in a mere dropping of the eye-lid, but that at the same time that the eye-lid descends, the globe of the eye ascends, and even mounts to a very considerable height—to a greater height than the eye ever rises to when employed in vision. The motion to which I refer was first pointed out by Sir Charles Bell, and proved, by a course of ingenious observations and experiments on living animals, to result from the alternate action of the inferior and superior oblique muscles, and to be independent of the action of the recti. In the patient Kearsley, this revolving motion of the ball of the eye remained unimpaired, because the nerves that regulate it proceed from within the orbit; so that when he winked, although the eye-lid did not perform its share of the

action, the globe of the eye executed its part, and ascended towards the lachrymal gland. Now it is not difficult to understand how the motion of the eye here described should have the effect of communicating a motion to the eye-lid that might be mistaken for the muscular action of the orbicularis. We have, in the first place, to recollect that the cornea forms a considerable prominence in the front of the eye, and that the margin of the lid even rests upon its convex surface. As the eye-lid, in consequence of the paralysis of one of its muscles and the relaxed condition of the other, in the present instance was quite passive, it is obvious that, upon the eye-ball being elevated, it would be carried up along with it. But the eye-ball could not elevate the lid to any considerable extent, without causing it to receive a sudden check when it had reached its highest point of ascent: by this means the elasticity of the ciliary cartilage, contained within the eye-lid, would be brought into operation; it would recoil, and the eye-lid would again slip over the eye. An additional circumstance is to be remarked: when the prominent cornea passed beneath the margin of the stiff eye-lid, it would meet with some obstruction, and have to push the cartilage forwards to some extent. This would necessarily cause a certain degree of tension in the eye-lid; its elasticity would be brought again into play, and, when the tension was relieved, the eye-lid would glide downwards by its own resiliency, and with an impulse resembling the action of the orbicularis muscle.

Before leaving this subject, I may revert to the revolving motion of the eye-ball here referred to. It is not for a moment to be supposed that this action of the eye has any particular connexion with affections of the *portio dura*: the only circumstance that may associate it with such cases, is, that as disease of this nerve causes the eye-lids to remain apart, the rotation of the eye is more easily observed in them than on common occasions. The rolling motion of the eye-ball takes place every time we wink, or when we close the eyes in dropping asleep. It is owing to it, principally, that we experience that aching sense peculiar to drowsiness, when an almost irresistible disposition to turn the eyes upwards, as well as to close them, seizes upon us. But the

motion may be observed likewise in a person fainting; as I have witnessed it, with a more appalling expression, in a patient dying. There are, nevertheless, some authors who profess to believe that no such motion of the eye-ball as that on which I have been dwelling ever takes place. Had these gentlemen seen the eye, in this case, travelling upwards to such a degree that the cornea was completely concealed behind the raised eye-lid, and the white part alone exposed, no doubt they would have attributed it to the injury received by the brain—called it a symptom of effusion—applied the term *strabismus* to it, or perhaps described it as a singular spasmodic disorder of the superior rectus muscle, heretofore unobserved by pathologists.

I beg now to draw attention to the observation, that after the patient had enjoyed the power of closing the eye in the manner that I have endeavoured to explain, he gradually lost it upon recovering from his state of coma, and the eye was in consequence permanently open. That this change did not take place from the power over the muscles of the face becoming diminished, was obvious, because at the very time that it occurred a manifest improvement was observed in their general condition. Two causes, it appears, tended to produce this new feature in the case. First, in consequence of the *levator palpebrae* being unopposed in its action, and the patient resuming the exercise of the eye in vision, it is natural to conceive that this muscle would acquire a power of contracting to a disproportionate degree, from which cause the margin of the eye-lid would be elevated to a higher level than formerly; and consequently it would be removed from the influence of the revolving motion of the globe of the eye, to which I have attached importance as causing its descent. But another circumstance may have contributed to produce the same effect. In the natural condition, the eye is held within the socket, balanced as it were, between two opposing forces; at its back part it has a bed of fat and cellular substance, which tends by its elasticity to thrust the eye forwards, while on the other hand, the eye is supported and confined within the orbit by the *orbicularis oculi* acting on its fore part. It follows that when the last-mentioned muscle is deprived of its power, the eye-ball will

advance to a certain degree, and become more prominent than the other. This is a condition of the eye which was not only noticed in the present case, but has been referred to as generally observed in affections of the portio dura. If it be allowed that this prominence might become gradually greater after the first accession of the paralysis, we may conclude that it formed an additional cause why the patient was unable, towards the end, to close his eyelids, although he had possessed that power at first.

Having thus had occasion to advert to the compression exercised by the orbicularis muscle upon the globe of the eye, I may be allowed to dwell a little longer upon it, as it may lead us to discover the design of a very peculiar structure in the interior of the eye, to which the action of this muscle seems subsidiary. It has to be remarked that the delicate textures of which this organ consists, are liable to be destroyed, independently of the effects of disease, not only by injuries proceeding from without, as blows, or the intrusion of foreign substances, but also by forces operating from within. This has been especially dwelt upon by Sir Charles Bell, in explaining why the orbicularis oculi should be under the control of the portio dura, a respiratory nerve. It will be seen that, although the action of this muscle has the chief share in defending the eye from both the sources of injury referred to, yet there is a beautiful provision in the eye itself for protecting its fine textures, that has hitherto been overlooked.

First let me attend to the action of the orbicularis. At all times the globe of the eye is compressed by this muscle to a certain degree; but at particular periods it is embraced and pressed into the socket much more powerfully than at others. If we watch these occasions, it will be obvious that the violent action of the orbicularis has a relation both to the respiration generally, and to the circulation of the blood within the head. When we cough, sneeze, blow, or strain in any way, we are sensible that, instinctively, or, as it were, spasmodically, we close the eye-lids, and brace the eye firmly in the socket. Now what is the condition of the circulation at these periods? It is familiarly known that the blood contained in the veins flows to the heart with different degrees of freedom, depending on the state of

expansion of the thorax; if the breathing be natural, the blood has an equable motion; if a deep inspiration be made, it is admitted in greater quantity than usual; but if, on the contrary, a full expiration be made, it is suddenly checked. Thus the variety in the capacity of the chest influences the admission of the blood to the heart, as it does the admission of the atmospheric air to the lungs. But as the veins of the neck and head are unprovided with valves, the interruption to the free course of the blood in the acts of respiration will be attended with more remarkable effects in them than in the veins belonging to other parts; the large trunks, for example, will be first over distended, and then a regurgitation will take place, reaching even to their minute branches. In a patient who had attempted to cut his throat, and only wounded the external jugular vein in the middle of the neck, I observed that as he coughed the stream of blood spirted upwards as high as the temple, as if the wounded vessel had been an artery going to the head, in place of a vein descending from it. This proves, what will be the condition of the eye, when we cough or sneeze, or perform any other violent act of expiration. The blood will be thrown back into the minute veins ramifying on the tender tunics, by which its soft humours are sustained; and, if not prevented, there will be the same turgescence in these delicate parts that we see exhibited in the red and suffused skin of the face and neck of an asthmatic. How admirably, then, is it provided, that the orbicularis oculi should act powerfully at this very moment, and press the eye-ball firmly into the socket, thus preventing the back current of blood from gaining an entrance into the interior of the eye. The necessity of this compression will be more strongly evinced when we consider what takes place in the brain; for it is to be remembered, that the veins of the orbit belong to those of the encephalon, inasmuch as the ophthalmic vein, after leaving the orbit, joins the sinuses of the brain; and it will accordingly be subject to the same impulses that are occasionally propagated through the veins of this organ. When a circular piece of the skull has been removed in trephining, or, in other words, when a portion of the brain has been deprived

of its uniform support, we have an opportunity of observing the nature and extent of the force which sometimes operates through the great venous trunks during the irregularities of the respiration. Every time that the patient breathes heavily, or struggles, or coughs, the dura mater will be seen swelling up to the level of the outer surface of the trephined hole, or, if the dura mater has been lacerated, a quantity of cerebral substance will be protruded on each of these occasions. As these phenomena are only to be accounted for by the blood being retarded in its flow, and consequently accumulating in the veins, and thus squeezing out the brain where it was unsupported by the skull, so may we suppose that if the eye were not duly compressed, its vascular membranes would be disorganized, from the over distension of its vessels.

But I have referred to another provision in the interior of the eye for assisting in the same object. It appears to me that the remarkable distribution of the veins in the choroid coat, which has obtained for them the term *vasa vorticosa*, is designed as an additional means of protecting the delicate textures composing this organ from the same dangers to which I have been adverting—that the force of the returning blood will be diffused and broken, by this peculiar arrangement of the veins, before it can reach the soft and easily-injured parts in which their minute extremities ramify. This appears to be the reason why the veins of the eye do not proceed directly backwards, in straight lines, but before uniting to compose a single trunk, describe those circular concentric sweeps so much admired in an injected preparation of the eye. This arrangement must cause the blood conveyed from the different vascular parts in the interior to flow, in the first place, in a contrary direction to the current in the larger vessels, so that it will oppose more effectually the impetus of that which is regurgitating. But the oblique manner in which these vorticeous vessels enter into the larger veins, towards which they converge, will also serve to check the course of the back current. The mechanism is, in effect, nearly the same that we observe in the veins of the brain, as they fall into the longitudinal sinus; and which, we can have no doubt, is provided to prevent these delicate vessels,

which are sustained in the interior only by the soft pulpy substance of the brain, from being gorged with the blood thrown back into the skull during forcible expiration*. In observing the course of these veins, as they ramify on the surface of the hemisphere of the brain, it is seen that they commence at the back part, and then advance forwards in an arched direction, till they fall with oblique openings into the longitudinal sinus. Now, if we exercise a little fancy, and exaggerate in our minds the curves described by the veins of the brain, we may consider the arrangement which they present as not differing greatly from that which exists in reality in the *vasa vorticosa* of the eye. In conclusion, I have to state that the opinion here expressed as to the uses of the *vasa vorticosa* is confirmed, if we observe the difference in the distribution of the veins in the eyes of fishes, as contrasted with the mammalia. The appearance that has given rise to the name is common to the mammalia; and these are all exposed, more or less, to interruptions of the breathing, as in contending for their prey, or uttering their wild cries, &c. They are consequently subject, also, to the irregularities in the circulation of the blood within the eye, such as we have been considering. But the fish, being a voiceless animal, living in a different element, never exhibits, by the expression of its features, or the movements of its body, any indications of its respiration or circulation being disturbed in a similar manner. Its apparatus for breathing and its circulating system, are, in fact, completely different from what we find in the mammalia. Accordingly, as the fish has no eyelids with which to close the eyes in a troubled state of his breathing, so I have not been able to find any appearance in the interior of the eyes corresponding with the *vasa vorticosa*; on the contrary, the veins which ramify on the choroid coat, in place of taking a vorticeous direction, run in straight lines like those of other organs.

* In a case of fracture of the skull, where the longitudinal sinus was wounded, the blood flowed in such torrents each time that the patient struggled or coughed, that I had much difficulty in restraining the bleeding, although it ceased almost entirely when he remained quiet.

REMARKS ON CHIRAYITINE,
QUINA, AND CINCHONAÆ.

To the Editor of the Medical Gazette.

SIR,

IT is the object of the following remarks to expose an imposition on the medical profession and the public: they refer to the professed discovery of a new vegetable alkaloid, called chirayitine, in the Indian plant *Gentiana chirayita*, Roxb. (*Causarra chirayita* Lam. and R. Br.) The pretended new substance has already been prescribed by several physicians, in the form of a sulphate, and the attention of the public in general has been attracted to it by repeated advertisements to the following effect:—"Chirayitine, a new vegetable alkaloid, discovered and procured from the Indian herb *Chirayita*, or *Chirattah*, by G. M. Mowbray. The inventor (!) begs leave to announce to the medical profession, and to whomsoever the above discovery may interest, that after a course of experiments, prosecuted during leisure hours for several years past, he has at length succeeded in discovering the aforesaid alkaloid. He has therefore prepared a quantity of the sulphate in crystals, for their use. Its properties and dose having been experimented on by several of the profession, may be known on application at his establishment."

Of this article I procured a portion from the discoverer. It was labelled as follows:—

"A new Vegetable Salt, perfectly soluble, having for its base the active principle of the *Chirayita* herb. Prepared by the discoverer, G. M. Mowbray. Dose $\frac{1}{8}$ to $\frac{1}{2}$ a grain.

"Brighton, A.D. 1837."

An examination of the substance, to which I proceeded, proved it, as well from its form of crystallization as from the results of the application of various tests (which I shall presently specify), to be the neutral sulphate of quina (commonly called bisulphate of quinine.)

The substance appears in colourless, transparent, rectangular, four-sided prisms; its crystals effloresce, and are soluble in from 11 to 12 parts of cold water; its solution has a purely bitter taste, and reddens litmus paper.

The crystals, when heated upon pla-

tina, melt like wax, and, by increased heat, change from a red to a black fluid, exhaling an empyreumatic odour, and leaving a combustible coal behind—a proof of the presence of an organic substance.

A heavy caseous white precipitate was produced when a recent infusion of gall-nuts was added to a solution of the substance under examination, thus indicating the presence of an alkaloid.

When chlorine and ammonia were added in sufficient quantity to a solution of one grain of the alkaloid in 1000 grains of pure water, with the addition of a few drops of diluted sulphuric acid, the solution assumed a beautiful green colour, peculiar to quinine, indicating the presence of the latter.

Caustic potash produced a white flocculent precipitate, which did not crystallize, and restored the blue colour to reddened litmus paper.

Phosphate of soda added to a concentrated solution of the alkaloid, turned the fluid into gelatine.

Sulphate of barytes gave a white precipitate, not soluble in muriatic acid, proving the presence of muriatic acid.

The application of these tests implies the nature of the substance to be a sulphate of quina, and not a peculiar alkaloid of the *Chirayita* herb, as asserted by the discoverer. These experiments have been carefully repeated, and compared with others referring to sulphate of quina, so as to remove every doubt upon the subject.

Does the herb *Chirayita*, then, contain quina?—a most interesting question, since that alkaloid has only been found, hitherto, in the *Cinchona*.

According to Mr. Mowbray's verbal information, twenty-eight pounds of the herba *chirayitæ* yield three ounces of the sulphate salt; therefore an ounce of the herb will contain about three grains, which quantity is sufficient to ascertain by test the nature of the substance. An ounce of the herb was procured from the discoverer, and submitted to the following process, in order to extract the alkaloid in question. The herb was well bruised, and boiled with eight ounces of spirit of wine, and twenty drops of diluted sulphuric acid; the spirit was pressed from the herb, and filtered, and evaporated in a water-bath, the residue dissolved in water, and diluted ammonia added, until litmus paper remained but slightly reddened.

An ounce of a pale-coloured fluid was obtained, which evinced no trace of an alkaloid by the application of a recent infusion of gall-nuts, a test which will indicate with certainty 1-25,000th grain of sulphate of quina. It is superfluous to add that other tests of quina give a negative indication. A friend, who first called my attention to the above substance, and who is known as a skilful manufacturer of alkaloids, experimented on many pounds of the herb to produce the new alkaloid, and I can affirm that he also could not find a trace of an alkaloid.

The foregoing experiments prove that the pretended new alkaloid is nothing more than the commonly called bi-sulphate of quinine, and that the herba chirayite does not contain a trace of that alkaloid. Thus much for the public good, and for the sake of truth.

It may not be here out of place to notice a few tests for quina, with reference rather to their delicacy and peculiarity than to their novelty. The sensible action of tannin upon alkaloids has been observed by many chemists, and particularly since J. Pelouze published his interesting treatise upon tannin (*Ann. de Chem. et Pharm.*, l. iv. p. 337-365). O. Henry has applied pure tannin as an alkalometer. From my own experiments, I have found that a recently prepared infusion of gall-nuts will indicate with precision the presence of 1-25,000th part of a grain of sulphate of quina, and will produce, after a few hours, a flocculent sediment. Even the 1-50,000th part of a grain of the alkaloid will be indicated, after being in contact for a few minutes with the infusion of gall-nuts, by a turbid appearance of the fluid; but this I may almost call the limit of dilution for the test. It is to be remarked that by such dilution of the alkaloid, the fluid must be kept neutral. To be able to place reliance on the delicacy of this test, it is quite necessary to make use of a recent infusion; for if the infusion is but a few days old, and has been exposed to the atmospheric air, it displays no re-action whatever upon the alkaloid, in consequence of the change of the tannin into ellagic and gallic acids, both of which will be deposited. But though the fluid still contains a portion of unchanged tannin, yet from the presence of gallic acid, a portion of which is held in solution, the formation of a tannate

will be counteracted, or the formed tannate of the alkaloid will be dissolved by it. The proof of the foregoing is, that quina will not be precipitated by gallic acid, and the fresh precipitated tannate of quina will be *readily* dissolved by the addition of gallic acid. Morphia is particularly sensitive in this respect, as a small proportion of gallic acid accompanying the tannin, will be sufficient to prevent the precipitation of the tannate of morphia; the consequence of which has been, that even eminent chemists have asserted that pure morphia could not be precipitated by an infusion of gall-nuts, and have established this apparent fact as a distinction between the above alkaloid and the narcotine which was readily precipitated thereby. When sulphate of quina is dissolved in water, and a few drops of diluted sulphuric acid are added, it is well known that the fluid becomes slightly blue; and I have found that this phenomenon can be clearly observed even when the fluid contains but 1-25000th part of a grain of sulphate of quina. This phenomenon may (conjoined with other tests) be received as evidence of the presence of quina. A remarkable and very peculiar test of quina, is that which was first remarked by Roper (*LONDON MEDICAL GAZETTE*, Dec. 1832, p. 320-321), and afterwards noticed by André (*Journ. de Pharm. Mars 1836*, p. 127, 137). It is the action of chlorine and ammonia upon a solution of quina, producing an emerald green colour peculiar (amongst the alkaloids) to quina alone. As this is one of the most decided tests for quina, which will ascertain 1-5000th part of a grain of sulphate of quina, I will here notice the caution which is necessary in its application, that it may be safe even in the hands of the inexperienced. To an aqueous solution of quina are to be added a few drops of diluted sulphuric acid, until that bluish hue which I before mentioned is produced. Chlorine gas is now to be slowly introduced (from a suitable apparatus containing chloride of lime, to which has been added a sufficient quantity of hydrochloric acid), until the blue circle which appears on the surface of the liquid (and which is plainly perceptible if the surface of the liquid be glanced at in a straight line) is destroyed. Liquid ammonia is yet to be added by drops, until that beautiful green colour is produced.

If this manipulation be carefully attended to, 1-5000th part of a grain of the alkaloid will be detected. If the solution of quina be concentrated, a greyish-green precipitate will be produced. A superfluity of chlorine will alter the quina, and, by the addition of ammonia, a brown colour instead of a green will be produced; which is particularly the case with a minute portion of the alkaloid. If the solution of quina contains colouring or extractive matter, the peculiar re-action cannot be produced unless it be freed from those substances; which cannot be done by chlorine, without partially or wholly altering the quina. To free it from those substances in some other way, according to their respective character, is therefore indispensable.

To ascertain an admixture of cinchonia in the quina salt, I found the following procedure satisfactory:—Two grains of quina are to be shaken in a phial, with one drachm of pure ether and one drachm of liquid ammonia of the usual strength; if the quina contain but 0.1 of a grain of cinchonia, the latter will be seen separated between the surfaces of the ether and the liquid ammonia, while the quina will be kept in solution by the ether. The separation of the cinchonia is caused by its difficult solubility in pure ether.

G. SCHWEITZER.

Brighton, Oct. 1837.

ON INJURIES OF THE EYE BY PERCUSSION CAPS.

By SAMUEL CROMPTON, Esq.

THE following observations were made in the practice of Mr. Barton, surgeon to the Manchester Eye Institution, to whom I am indebted for permission to publish the illustrative cases, and his method of treating them.

One of the fragments, into which a percussion cap breaks when it is exploded, sometimes enters the eye. The accident generally occurs in shooting with, or in discharging, percussion caps with a hammer. I have seen many instances of it, and have preserved notes of seven cases, in each of which the injured eye was destroyed. In one of these cases the vision of the other eye, also,

was nearly lost, from sympathetic inflammation; and it is most likely that there would have been a similar termination of the rest, if that treatment, which I shall presently describe, had not been adopted. The peculiarities and importance of these injuries, and the consideration that they are unnoticed by systematic writers on the eye, have induced me to detail, more minutely than would have otherwise seemed necessary, the most remarkable circumstances relating to them.

In every case the fragment of cap was driven into the posterior chamber of the eye; but immediately after the accident, the changes produced in the eye, and the symptoms, were so like those observable in penetrating wounds of that organ, when no foreign body remains in it, that it was impossible to ascertain, at first, whether the cap was in the eye or not. The wound made by the entrance of the fragment of cap into the eyeball was generally a clean incised one, and healed readily. The vision was not destroyed immediately in those cases in which the cap went through the sclerotica, and did not injure the transparent parts of the eye. For a length of time, varying from a few days to a month after the accident, the patients appeared to be in a fair way for immediate recovery; but at the expiration of that time they were suddenly seized with most acute pain in the eye, attended with extensive chemosis, and with haziness of the cornea in some of the cases. Suppuration never happened. The pain subsided entirely for a while, or was greatly mitigated in a day or two after its commencement; but this cessation was only temporary, for it always recurred and subsided at uncertain periods, until the vision with the injured eye was entirely destroyed, the eyeball in a state of painful chronic inflammation, and the health of the patients much injured by the irritation occasioned by the injury, and from anxiety for their sight; for the vision of the other eye became affected at this stage of the disease, by the inflammation extending to it by sympathy. The first indications of its commencement there were a slight redness of the conjunctiva, and an inability to see so well as formerly with the eye, or to bear the ordinary light of a room without pain and confusion of vision.

In Case I. the effects of the symp-

thetic inflammation were, a dull yellow colour of the sclerotica; a change in the colour of the iris, and adhesion of it to the capsule of the lens; and a very irregular and small pupil, filled with a dot of opaque capsule.

The fragments of caps taken from the eye, after being within it for months, were only tarnished; they bore no appearances of undergoing changes similar to those which take place in pieces of steel during their exposure to the humours of the eye; they were always of a considerable size, and their angles were very sharp. Mr. Barton believes that the sympathetic inflammation in these cases is occasioned by the presence of a fragment of cap in the other eye, and that the only means of preventing it, or of allaying it when it has arisen, is the removal of that fragment from the eye. He has treated many cases on this principle; of seven of which I have preserved the following notes.

CASE I.—W. —, Esq., about forty years of age, and of very intemperate habits, was shooting on the moors in August 1832, when, on discharging his gun, something cut his right eye. He lived far from Manchester, and was under the care of his usual medical attendant, who used active measures to subdue the pain and inflammation which occurred in a few days after the accident. He consulted Mr. Barton, for the first time, on the 29th October, 1833, when he had continued pain in his right eye, occasionally so severe as to prevent him sleeping for successive nights; his vision with it was destroyed; the left eye also was inflamed sympathetically, and vision with it so much impaired that he could not find his way. His health had suffered greatly from the effects of the disease, and his anxiety for the recovery of his sight. Mr. Barton told him that it was very probable that something had entered the eye and occasioned his sufferings; but, in compliance with the request of the patient, who was unwilling to submit to an operation for its removal, various plans of medical treatment were tried until the 3d of November, without the least benefit being derived from them. On this day a large piece of the cornea of the left eye was cut away, in order to remove the foreign body; but the eye was so exquisitely sensitive,

that attempts were not made to find it. A large poultice was applied to the lids. In a few days afterwards a large fragment of a percussion-cap was removed from the coagulum, which filled up the opening that had been made in the globe of the eye; it was merely tarnished, and its angles and margins were as sharp as if it had been just broken. The patient was permanently relieved, but the sympathetic inflammation had produced so great changes in the other eye, that it was necessary to perform an operation for artificial pupil upon it.

CASE II.—George Ankers, of Staly-bridge, about 28 years of age, on the 29th January was sitting near a man who discharged a gun, when a portion of cap entered his right eye. On the following day he could see across a room with that eye, but in the course of a month vision with it was quite lost. On the 8th April the conjunctiva was very vascular, and the eye occasionally very painful. He could not bear the ordinary light of a room without placing his hand over the other eye (the left), neither could he read more than one, two, or three lines with it, before the letters became indistinct, and the eye painful. A flap of the cornea of the right eye was removed, and a poultice was applied to the eyelids. On the 16th of June, a friend removed the fragment of cap from the cicatrix in the front of the eye-ball. He has been easy since, and the powers of the other eye are quite restored.

CASE III.—Master R., of Stockport, about six years of age, was playing, on the 25th of July, 1836, with a boy who was exploding percussion caps with a hammer, when a fragment of one cut his eye. This eye was so free from pain and inflammation for several weeks, that it was hoped that the cap had not entered it; but by the 21st of September it had assumed the appearances indicative of its presence there. A portion of the front of the eye-ball was cut away. On the following morning the fragment of cap was found in the poultice which had been applied to the eye-lids; it had only become of a darker colour by being in the eye.

The following cases were treated as the above:—

CASE IV.—W. Williamson, of Stockport, injured in shooting.

CASE V.—Adam Chamley, of Hebden Bridge, Yorkshire, injured in shooting.

CASE VI.—Mr T., of Cumberland, injured in shooting.

CASE VII.—John Taylor, of Manchester, injured whilst standing near a man exploding a percussion cap with a hammer.

The details of the four last cases are so like those of the three first, that it seems unnecessary to give them. In all, however, the object of the operation was gained; the sympathetic inflammation being suspended in the first case, and the symptoms which were thought to indicate its approach being removed in the others. The operation is thus performed:—The patient being placed in a convenient position, the operator forms, by means of Beer's knife, a large flap of the cornea, which he seizes with the forceps and cuts away with a pair of curved scissors. A dose of laudanum is then administered to the patient, and a linseed-meal poultice applied to his eye-lids. The operation always gives great pain, and should be performed as rapidly as possible. The eye is so exceedingly sensitive, that attempts to find the fragment of cap cannot be endured. In all the cases of Mr. Barton, the cap was found in the poultice, or in the coagulum which closed the opening into the eye, in a day or two, or at a longer period after the operation.

I have made diligent inquiries as to whether the caps which inflicted the injury were grooved or smooth. I believe that they were generally smooth and of an inferior kind, called French caps; but it is very likely that both kinds are very dangerous when exploded between two flat surfaces on a level with the eye; an amusement with children which is very common in this part of the kingdom.

Manchester, Oct. 21, 1837.

POISONING WITH CREAM OF TARTAR.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think the following account of a case of poisoning, from taking a large quantity of cream of tartar, worthy to be recorded, I would beg the

517.—XXI.

favour of its insertion in an early number of the *MEDICAL GAZETTE*.

I remain, sir,

Your obedient servant,

WM. T. TYSON,

M.R.C.S. L.

57, Ossulston-street, Somers Town,
October 22, 1837.

John Hudson, æt. 37, residing at 24, Southampton-street, Euston Square, employed by the notorious and self-styled *Dr. Morison*, at his pill establishment in the New Road, King's Cross.

On Tuesday evening, Oct. 10, he returned home extremely weak, and scarcely able to walk. He stated that he had been severely purged, had at least had twenty-five motions, attended with constant vomiting. On the previous day (Monday) he was drunk. The nurse told me, that one of Morison's men said he was sure Hudson had taken nearly a quarter of a pound of cream of tartar at one time, and that during the day he was continually putting small lumps into his mouth, to cool his stomach. The nurse also noticed a quantity of white substance at the bottom of the chamber utensil; she then asked him if he had been taking any salt. It was unfortunately thrown away.

11th.—At twelve o'clock he was seen by a medical gentleman, who found that during the night he had been repeatedly purged, and suffered greatly from constant vomiting. He complained of pain in the umbilical region, and of great thirst. Tongue brown and dry; pulse feeble; pain in the loins. The thighs and legs appeared paralysed. The fluid vomited was of a blackish green colour, and the motions of the colour of coffee-grounds. He stated that he had taken four or five table spoonfuls of cream of tartar, which is a principal ingredient in Morison's cooling powders. An opiate was given to him, which afforded slight relief; but the symptoms returned, and he died on Thursday at noon.

14th.—I was requested to assist in making a post-mortem examination of the body. He was a strongly-built, well-formed man, stout and muscular; no spots or bruises upon the body. The fat covering the abdominal muscles about half an inch thick.

Stomach.—This was distended with gas, and contained about three ounces

N

of a thick brown fluid, coloured apparently with bile. Near the pylorus there were several red patches. The cardiac end of the stomach was very much inflamed, the mucous membrane being of a deep red colour, with three or four spots of a blackish red, as if from rupture of some of the minute blood-vessels. The mucous membrane of the duodenum was also of a red colour in many places, but not in so great a degree as that of the cardiac end of the stomach; it contained, apparently, the same kind of fluid as the stomach. A portion of the small intestines, as also the colon, had the mucous membrane reddened. The mucous membrane of the rectum was injected in small streaky red patches; where there was no redness, the membrane was of a white colour. The intestines contained a thick brownish kind of mucus; no fecal matter was observable throughout their whole extent. A great deal of fat was attached to the large intestines, and the omentum contained a large quantity.

Chest.—The lungs might be termed healthy, though there were adhesions at the posterior part of the lobes of the left side, and at the anterior part of the lobes of the right, evidently of an old formation.

Heart.—A great quantity of fat about the pericardium. The heart was unnaturally large and flabby; the lining membrane of the left auricle was of a deep red colour, as also the lining membrane of the aorta and semilunar valves. It weighed 13 oz.

Liver.—Large and very firm. On cutting it an oily appearance was left on the knife, and oil could be scraped from the cut surface. It weighed 4 lb. 11 oz.

Spleen healthy. Kidneys large, and embedded in fat.

LARGE EXOSTOSIS OF THE FOOT.

To the Editor of the Medical Gazette.

SIR,

By inserting the following case of exostosis of the foot, you would much oblige,

Your very obedient servant,

THOMAS FALCON.

Bradford, York,
Oct. 23, 1837.

Samuel Bradley, by trade a weaver, 32 years of age, of a leuco-phlegmatic temperament, says that the above exostosis first made its appearance about fifteen years ago, and has gradually increased to its present enormous size.

The tumor completely envelops the whole of the foot, both on its dorsal and plantar surface, its circumference being about eighteen inches. That portion of the tumor situate at the internal border of the foot is slightly moveable on its base, and apparently cartilaginous or gelatinous in texture; but in the middle and outer part of the foot it is immovable and osseous. There are two ulcerations on its dorsal aspect, from which spiculae of bone have been extracted. The patient has never experienced pain, nor had any constitutional symptom indicative of the tumor being of a malignant nature.

He had previously consulted three surgeons, who declined to remove the tumor, and said that amputation must be had recourse to. The patient objected to lose his leg, but was willing to submit to the removal of the tumor. From his history of the case I was led to infer that the growth of the tumor first commenced either from the cuboid or external cuneiform bones, or from the heads of the three outer metatarsal bones.

I gave it as my opinion, that the tumor was attached by bone (and inseparable) only at the outer part of the foot, and that there would be a portion of the foot remaining, after the operation, sufficient for the support of the body and progressive motion. Having obtained the man's consent, I first removed the tumor in the manner hereafter described, and then a portion of the foot, by the method described by Mr. Wharton before the Medical Association at Dublin.

Operation.—The first incision commenced at the intermediate space between the second and third toes, and a little above their junction with the metatarsal bones (viz. from the point marked *a*, in the drawing, in a straight and longitudinal direction to the point *b*.) From these last points two incisions were made at right angles, viz. from *b* to *c*, and from *a* to *d*, and the integument reflected inwards, so as to be enabled to obtain a covering for the two

FIG. 1.

FIG. 2.

first metatarsal bones (on their dorsal aspect.) Another incision was then carried from *b* to the anterior and inferior border of the os calcis, viz. at *g*. The portion of the tumor included in the quadrilateral space marked *a b c d*, being cartilaginous, was separated from the tendons of the tibialis anticus, extensor proprius pollicis, and that portion of the tendon of the extensor longus digitorum going to the second toe, and removed by a strong knife. Another incision was then made, commencing at *a*, and extending to *g*, on the under surface of the projecting part of the tumor. The portion of the tumor situate in the triangular space *a b g*, was then separated from the three outer metatarsal bones, the cuboid, and the external cuneiform bone, by Hey's saw. The part of the tumor extending into the sole (which was cartilaginous) was then carefully dissected outwards, and separated from the abductor pollicis pedis, flexor brevis digitorum pedis, and the internal plantar artery and nerves. A catlin was then passed between the second and third metatarsal bones, and thence forwards between the external and middle cuneiform bones. Laying hold of the three outer metatarsal bones with the left hand, and placing his foot on my knee, I used it as a fulcrum to dislocate the cuboid and external cuneiform bones from their articulatory surfaces with the os calcis and scaphoid. Then, by dividing the calcareo-cuboid, ligamentum longum plantæ, and the

deep-seated calcareo-cuboid ligament, completed the operation.

A considerable portion of the flaps united by the first intention; the remainder granulated, and cicatrized favourably.

Fig. 2 represents the foot after the operation, and the numerals 1, 2, 3, the line of the cicatrix.

At the present time (three months since the performance of the operation) he is able to walk upon the limb. The tumor, after its removal, weighed five pounds.

MEDICAL GAZETTE.

Saturday, October 28, 1837.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum -it, dicendi periculum non recuso."
CICERO.

ON THE SUPPLY OF SUBJECTS FOR DISSECTION.

THE medical session has scarcely commenced, and even now there is a complaint of the inadequacy of the supply of subjects for prosecuting anatomical studies—already the inexpediency of the system at present adopted under the Anatomy Act has become evident. This is only in accordance with the experience of past

years, which has clearly shown that the only advantage (as far as the student is concerned) of the plan now pursued for obtaining bodies, is their greater cheapness; an advantage which is, of course, more than outweighed by their scarcity. Under the old system there was never any difficulty in obtaining as many subjects as the pupils would pay a large price for; whereas now that no amount of expense or trouble is of any avail, the supply falls miserably short.

But we do not believe that this deficiency is the necessary result of the Anatomy Bill *per se*. Had it been left to be worked out in strict accordance with its letter, it would have continued to afford still, as it did at first, a supply fully sufficient; but interfered with as it has been, by the introduction of fresh powers and of artificial expedients of distribution, it has been made useless, if not mischievous. The original cause of the failure of the last four years is probably in the recollection of many of our readers. In 1833, previously to which there had been a plentiful supply under the act, complaints were raised by some of the teachers that there was an unequal distribution among the different schools, and that this would necessarily, in the end, be injurious to those least favoured by fortune or by influence. The fact was, that many of the teachers had been using all the interest they possessed in different parishes to persuade the authorities to assign the unclaimed dead for dissection, and had in many instances succeeded in inducing them to grant that they should be so, provided they were sent to, and dissected at, certain schools in whose managers they (the authorities) could confide. By these exertions many of the schools obtained a sufficient supply; but no sooner did the others who had less influence, and received only their share from the general stock consigned to the Inspec-

tor, find themselves at all deficient in their supply, than they cried out for an equal distribution of all the bodies, to whomsoever consigned, according to the number of pupils in each school requiring to dissect. The immediate and very natural effect of this was, that in some of the parishes the authorities refused to give up the bodies, and preferred to have them buried at the parochial expense, rather than risk their not being buried at all. Others became indifferent, when they had not the power of obliging their own friends; and the exertions of the teachers, which were well repaid when all the subjects they obtained were sent to their own or only a few schools, were discontinued now that the same number of subjects were divided among twenty different establishments.

Ever since, the supply has been smaller in all the schools than it was in any of them previously to this interference. In 1836, the occurrence of the influenza, and the consequent number of deaths in the large hospitals, gave the schools attached to them a temporary surfeit; and accidental causes have at other times, for a short period, favoured them; but, with these exceptions, the deficiency has been universal, and the prospects for the ensuing season are worse than ever.

The chief cause of all the difficulties is evidently this imagined necessity for equal distribution, which, even if it existed, would be no compensation for the loss it occasions; for surely it were better that some should be served well, and others moderately, than that all should fare intolerably ill. In the first place, how is this equal distribution effected? Why, from each school there is to be sent to the Inspector a written account of the number of pupils intending to dissect there, and according to the proportion of the members thus ascer-

tained, the bodies are distributed. If, for example, from one school a return of twenty, from another of thirty, from a third of forty pupils were obtained, they would severally receive in return, in the proportions of two, three, and four, from the whole stock of subjects obtained. The objections to this method are palpable enough. From some schools, lists, all but fictitious, are sent in: pupils who have long since received their diplomata; pupils who do not intend to remain in London more than a few weeks; all that can be pressed into the service, subscribe their names to swell the list of those who it is pretended intend to dissect; and the greater the degree in which this dishonesty is practised, the greater is the reward. If, on the other hand, a teacher sends in a fair list, or if (as is often the case in large schools) he cannot easily obtain the signatures of all his pupils, and at all neglects to make out his fullest number, he suffers for it by a proportionate loss. Besides, this plan applies only to the pupils, not to the lecturers, who need as many subjects for a small as for a large class; and according to it, if the teacher of 120 obtained six subjects for his lectures and demonstrations (which are not more than is necessary,) the teacher of twenty would have but one for both courses for the whole season.

Nor are these the only objections that must always mar the present system of distribution. Of all schemes in political economy, none have more invariably met with signal failures than those of attempting to regulate supplies by imagined wants; and the present will only add another to the number experience has already seen fail, even when undertaken on far better data than are at present attainable. To say nothing of the somewhat inquisitorial plan of demanding from each teacher the number of his pupils, and

so of holding up to the public the degrees of success or failure of each school, this mode of supplying by number, without regard to condition or want, is utterly absurd. An inspector might as well attempt to determine by the number of customers which each butcher or baker had, at the beginning the year, how many oxen the one should be allowed to buy at Smithfield, or how much flour should be supplied to the other at Mark-lane, and restrict each to what he deemed sufficient, till all his brethren were served with what seemed a fair quantity and quality, according to their lists of customers. Our authorities may depend on it, neither teachers nor tradesmen will ever procure more of their commodities than they can fairly dispose of; and they are themselves both the best judges of what they want, and the best able to obtain it: besides, the perishable nature of the commodity here considered, is sufficient to prevent any attempt at monopoly. When Government appoint persons to do that for others which they can do sufficiently well for themselves, dissatisfaction is sure to arise, and failure must follow; and this is just the course which the system, employed under the Anatomy Act, is now taking.

At present, however, no exertions seem to be used by any one, and the parishes and other sources from which the principal supply should come, are left to give their unclaimed dead or not, as they like. The authorities in several places still dislike disposing of their fellow-creatures for such purposes; some fear popular clamour; others think the small pecuniary advantage of saving the burial fees insufficient to compensate for the trouble; and all are cold and indifferent to that in the advancement of which they have no immediate interest*.

* There is a man of the name of Roberts, who, disappointed at finding no patronage for

The Poor-Law Bill, too, thins the number of living in the workhouses, and so indirectly affects the dead. But all these difficulties might be overcome by private exertion, by any one who would act in one case on the common sense, in another on the interest, in another on the friendship of the parties concerned; here asking favours, there promising benefits in return, and always assuring the fulfilment of all the Act requires. These, and these only, are the means which, actively employed by private individuals, will secure a sufficient supply of subjects of dissection; and if they be not permitted, we can scarcely expect but that many of the abominations of the system that existed before the Act was passed, will return.

But what encouragement is there for those teachers who, previous to 1833, shewed, by the supply they obtained, how great influence they possessed, to continue their exertions, when, after all the trouble and expense they have incurred, they see that supply which, in the mass, would have been valuable for one, broken into twenty morsels, in a vain pretence of satisfying a multitude, among whom are all their own opponents? Even exertions made in private practice are now useless; for where the friends of a deceased person would give up the body to any teacher whom they were on terms of intimacy with, it is not probable they would let it be carried they know not whither, or to what destiny. In short, individual private exertion is totally disabled, and all have given up attempting to employ any; and to expect a co-operation of such conflicting interests as those in the various schools, is a chimera

what he absurdly thinks a valuable discovery for preventing putrefaction, endeavours to prevent the schools being supplied, by addressing to the guardians of the poor the most ridiculous misrepresentations "of the disgraceful manner in which the bodies are treated," and who placards the streets with warnings against Dr. James Somerville, and the anatomical teachers.

to demonstrate the fallacy of which the angry feelings excited in 1833 were not needed.

Had the present difficulties been foreseen when the bill was being framed, a clause might have been introduced to appoint some person, or means that should have constantly acted, to insure the greatest possible supply from all the sources open; for it was the professed object of the bill not only to prevent the repetition of the indecent outrages and crimes before perpetrated, but to afford all necessary legal assistance to the study of anatomy, for which previous statutes had been found insufficient. Had all the government and other influence been thus fully secured, it might have been the rational duty of an inspector to distribute the full supply that would then have been procured; but in the present case this power given to the inspector cripples private exertion, and brings with it nothing as a compensation. We know that many think it is the duty of the present inspector, not only to see all the requirements of the act fulfilled, and to effect a just division of the bodies, but also to procure a sufficient supply for such distribution. But in the Act no such power is given him; neither is he mentioned as the proper person to do this; nor is any mode of obtaining a supply pointed out. To add this to his other labours is quite absurd. If those who made themselves dependent on his bounty thought that they had placed themselves in the power of one who could pay them well, and had riches both in hand and in prospect, they were much mistaken. He is in no way obliged to procure a single body for dissection—nay, even his right to distribute them is rather questionable; and the only duties actually required of him by the Bill, are to see that all the matters relating to the receiving and burying of bodies are accomplished according as it ordains.

He complains, we understand (and we have no doubt with justice), that his situation is already most painful and most arduous, assailed as he is every day by importunate lecturers who have no *subject* to descant upon. This distributing part of his functions, too, is doubtless the more annoying, as in it he exercises a power which he did not originally possess, or at least exert, but which was almost forced upon him, in 1833, when, in the hope of assuaging the disputes, he undertook to manage this division of the bodies among the several schools. We can easily imagine that at that time he little imagined what an unpleasant task he had undertaken, and that he little knew how impossible it would be ever to please all those whom he had made the beadsmen of his bounty. Had he all the living as well as the dead to dispose of, he would scarcely satisfy them of his justice, though he might of his liberality; but in his poverty of resources, we can scarcely conceive any man more miserably pestered than he must be every day of his life. We would strongly recommend him to give up the little authority his power affords him, and which is dearly bought at the expense of being subjected to such perpetual and irremediable annoyances, and to let his office lapse back again into the comparative sinecure of receiving and arranging confidential returns and burial certificates.

If the clog of distribution were removed from them, we feel assured the teachers would each find for himself a sufficient supply; for, as we have said, exertions which never will be employed for the general good would soon be actively made for private advantage.

The only ill effect which has ever been feared from this return to the old plan (but that it would follow has never been proved) is, that the small school's

would suffer in consequence of the whole supply being absorbed by the larger ones; and that some of those possessing least influence must be altogether "swamped." It is not for us to fix the value of some of these institutions, nor to say how much the public or the profession would suffer, if some of the lowest on the list were altogether expunged, but assuredly, if in order to serve them the whole body of students are to be prevented from learning anatomy efficiently, the sooner such schools are closed the better. But we do not believe such would ever be the result; there cannot be a teacher without sufficient interest in some parish to obtain a share of the bodies, and there will always be a certain number consigned to the inspector, which it would be his especial business to distribute among the worst supplied schools. But further—can they be worse off than they are now? The dissecting rooms of some are empty and inodorous; while those of others are so odoriferous that they had better be emptied as soon as possible; demonstrations are being given without subjects; and all real anatomy is at a stand-still.

In short, the present system being irksome to both teachers and inspector—injurious to the large schools—ruinous to the small ones—and an insuperable obstacle to the study of anatomy in London—it will be for the advantage of all to give it up. *Let, then, the teachers memorialize the government*, stating their ability if left to themselves to relieve their own wants, and the impossibility of any but private exertions effecting the object: let this be done, and supported by the inspector—as we scarcely doubt they would be—they may almost rely on a speedy amelioration of their condition.

CLINICAL LECTURE

ON

VARICOSE VEINS AND ULCERS
OF THE LEGS;*Delivered at St. George's Hospital, Oct. 17, 1837,*

BY SIR B. C. BRODIE, BART.

Ulcers of the Leg depending on Varicose Veins—Importance of such Cases—Different Situations in which Varicose Veins occur—The Varicose state sometimes dependent on Pressure, but often independent of this, and probably arising from Weakness of the Coats of the Veins—Effect of Pressure and of the Valves—Progress of Varix—Symptoms which result—Inflammation of Varicose Veins—Peculiar appearance of Ulcers from this cause—Treatment of such Cases—Bandages—Plasters—Laced Stockings, &c.—Rest—Cold Lotions—Purgatives.

"MARY ANN RICHARDSON, 48 years of age, was admitted on the 11th of October, with ulcers on the legs. She has a group of three ulcers, each about the size of a shilling, situated in the middle of the left leg, on the outer side, with livid edges and flabby granulations, slightly elevated above the level of the skin, and discharging pus tinged with blood. There is another ulcer, of the same size and description, but with small indolent granulations, above the inner malleolus. These ulcers are reported to have commenced each with a small pimple, followed by a superficial abrasion of the surface, discharging a watery fluid, and afterwards extending into an ulcer. There are cicatrices from previous ulcers on the leg, and also the appearance of some of them in the first stage of their formation. She has suffered from these ulcers for nine months, and for some years from varicose veins, of which there are clusters on both sides, and smaller ramifications of them over the limb. The skin of the lower two-thirds of the leg has a dark stained appearance, with a defined margin."

This is a case in which there is no question about the patient's life or death, and I think it very probable that many among you may pass by the bed-side of such a patient without thinking it worthy of attention. But I am not disposed to regard it in this manner. Although the patient will not probably die of this disease, yet, without great care, it may render her miserable. The disease may be very much relieved by art, and it is one of very common occurrence. You examine carefully a case of aneurysm, a case of stone in the bladder, and so on: but these are

things comparatively of rare occurrence, and which, at any rate, will not fall under your treatment in the beginning of your professional lives. But here is a case of a very distressing nature, and such an one as may meet you at every turn of your practice; and your reputation in early life will depend more upon understanding a case of this kind, than upon your knowledge of one of more rare occurrence.

I have no doubt that the ulcers of the leg in this case depend upon the varicose veins. These are what we call *varicose ulcers*. In order that you may understand this particular case, I must make some general observations on varicose veins, and the ulcers to which they give rise. I shall first speak of the disease, then of the treatment required; and I shall leave you to apply the observations which I have made to the case now before you.

By a varicose vein, I mean a vein which is unnaturally dilated. When there is increased growth of any part, the arteries increase in size to take the blood to it, and the veins increase in size to take the blood from it. This is a healthy increase of the veins, and we do not call these veins varicose. But by a varicose vein I mean a vein unnaturally enlarged, without the dilatation being instituted to answer any good purpose in the animal economy.

Varicose veins occur principally in three situations: in the legs: in the spermatic cord, where the disease is called *varicocele*, or *circoscele*; in the rectum, and about the anus, where the disease takes the name of *piles*, or *hemorrhoids*. I will explain to you, by-and-by, why they occur in some situations more than in others. But varicose veins occasionally occur in other parts of the body. I have seen varicose veins of the forearm to a considerable extent. In the case to which I allude, there had been inflammation of the median cephalic and cephalic vein. These veins had become obliterated, and, in consequence of their obliteration, the blood did not easily return from the forearm; so that the veins became varicose.

A man was admitted into the hospital who had varicose veins all down the right arm, and to a considerable extent down the right side of the chest. He had difficulty of breathing, and cough. One day he felt as if he had received a blow on one side of the chest, and immediately a large abscess presented itself, as big as an orange externally, which had evidently made its way from the inside of the chest through one of the intercostal spaces. Immediately upon the appearance of this swelling, the varicose veins in a great measure subsided. The man died, and on examining the body after death, it was

found that there was disease in the bronchial glands; suppuration had taken place in them, and a large abscess had been confined in the inside of the chest, which pressed on the right subclavian vein, and this caused the blood to stagnate in the veins in which it had its origin, and which had in consequence become varicose. So, under corresponding circumstances, you may find the veins become varicose in any part of the body.

In the first of the cases which I have mentioned, the varicose disease was the consequence of disease and obliteration of the venous trunks; and such is sometimes the cause of varicose veins in the legs. There was a man in the hospital with very bad varicose veins of the legs, one of the worst cases of the kind that I ever met with. The man, however, was admitted into the hospital on account of another disease, of which he died. I examined the body after death, and found an obliteration of the external iliac vein. This vein had been inflamed at some former period, and had become converted into a thick hard cord. The blood could not flow to the heart through this great venous trunk, and so the branches below became varicose. In the other case which I have mentioned, pressure on the venous trunk was the cause of the varicose disease. And so pressure on a venous trunk in the abdomen may produce varicose disease in the legs. You have a very frequent example of this in child-bearing women. The pressure of the gravid uterus will produce varicose veins of the leg. The woman is brought to bed, the pressure is taken off, and the varicose veins in a great measure disappear. Then she becomes pregnant again; the varicose veins recur; she brings forth another child, and the veins in a great measure subside, but not so completely as before. Every time she is pregnant the varicose disease of the veins becomes aggravated, till at last it exists to a great extent in both legs.

There are a few cases in which we may trace varicose veins of the lower extremity to pressure or obliteration of the venous trunks; but in the majority of cases it must be acknowledged that we cannot trace the disease to these sources. It appears, in these cases, to be a mere weakness in the coats of the veins, rendering them incapable of supporting the weight of the body. There is, of course, always a column of blood pressing downwards when the patient stands erect; and if the coats of the veins are weak, this is sufficient to render them varicose. You will understand, then, why, when the coats of the veins are weak, persons of particular habits, or of a particular physical construction, are more liable

to varicose veins of the legs than others. A person who is always upon his legs, always standing or walking, is much more liable to have varicose veins of the legs than one who leads a more sedentary life, because there is here a column of blood almost always pressing on the veins below.

Sir Everard Home has observed, that in the army the grenadier companies are especially subject to varicose veins, they being taller men than the other soldiers. Cooks are very subject to varicose veins. Why? If you put one hand into warm water, and the other into cold, you know that the veins of the former will become dilated, and that those of the latter will contract.

But where the disposition to the disease exists, do all the veins become dilated? By no means. The deep-seated veins never become varicose, because there is the pressure of the muscles upon them on every side, which prevents their dilatation. It is only the superficial veins that become varicose. The branches of the vena saphena major, and sometimes of the vena saphena posterior, become dilated. But the valves do not increase with the dilatation of the vein; they remain of their original size; and what must be the consequence? Why, the valves do not protect the venous branches below from the pressure of the column of blood above; they do not answer the purpose of valves any longer; and the want of action in the valves tends, of course, to aggravate the disease. By and by the valves seem to become changed in structure; they shrivel up, and become at last good for nothing, not even looking like valves. This is in conformity with a general law of the animal economy: a part not used wastes. If you were to tie up one eye, and cover it from the light for many years, you would find at last that you could not see with it. Muscles not used will waste. So it is with the testicles and other organs. When valves become useless, nature does not seem to think them worth keeping, and they waste or shrivel.

In a few instances varicose dilatation of the veins comes on rather suddenly; I have known cases in which the veins in both legs became varicose immediately after very hard walking. But, in general, the disease comes on slowly, and increases gradually. At first one or two veins are a little dilated, and you see the dark blood looking of a blue colour through the skin. Then other veins assume the same appearance, and by and by you find clusters of varicose veins in different parts of the leg. The skin is elevated by the clusters underneath; and it is when the skin is strained and rendered thin that you see the dark

colour of the blood through it. These clusters are more frequently situated about the inner ankle, and the inner side of the leg, than any where else; but they may occur any where else, at the back or outside of the limb. Then, as the disease proceeds, it extends to the trunk of the vena saphena major, and this becomes dilated all the way up to the groin. Sometimes the saphena major looks as large as your finger, assuming a knotted appearance. What is the explanation of this? It would seem that the vein is tortuous. Varicose veins are not only increased in diameter, but in length, and of course must then be made tortuous; and where the saphena vein is twisted, as it were, upon itself, it assumes the appearance which I have mentioned. The dilatation of the vein is perceptible when the patient stands erect; but when he lies down the varicose appearance vanishes, because then the veins become emptied of their blood.

While these changes take place in the condition of the veins, the patient experiences more or less inconvenience. Sometimes he suffers from a sense of itching and weight about the inner ankle. The sense of weight and fullness becomes more troublesome when he takes a long walk, so as to be very distressing. Where there is a varicose cluster, the patient in a few instances experiences extraordinary pain, and this, as I imagine, arises from there being some nervous filament pressed on by the tumor. Sometimes the patient complains of being subject to cramp in the muscles of the leg, especially after a long walk. Varicose clusters occasionally burst and bleed. I said, in the commencement of the lecture, that the disease is not dangerous, but that is not absolutely and universally correct. There are a few cases in which a patient may be in danger from hæmorrhage. A varicose cluster becomes larger and larger; the skin over it becomes more attenuated, at last it gives way, and there is a great discharge of blood. I have heard of patients actually dying from this hæmorrhage, where assistance could not be procured. I have known a great many cases in which patients have lost a very large quantity of blood from such an occurrence; and I have heard of others in which death was the consequence.

Varicose clusters of veins sometimes become inflamed. They are then tender to the touch. Frequently the inflammation is preceded by a rigor, or by an attack of fever. In some instances the inflammation extends to the skin over the cluster, the skin becomes red, and if the patient stands up, he suffers great pain in the inflamed varix, but if he lies down,

the pain is in some measure relieved, though not entirely. The great pain in the erect posture is explained by the weight of the column of blood pressing on the tender parts.

In some cases inflammation of an inflamed varicose cluster will end in suppuration, and in an ulcer, but that is not the way in which ulcers connected with varicose veins generally begin. For the most part, the effect of inflammation of a varicose cluster is not to produce either abscess or ulcer. It is very remarkable that the blood in inflamed varicose veins coagulates, and the vein becomes choked up with the coagulum. There seems to be something in an inflamed vein that is unfavourable to the fluidity of the blood which it contains. You observe this not only when varicose veins are inflamed, but when veins are inflamed under other circumstances. You find this frequently in cases of piles. A patient comes to you with an external pile, which is large, and very tender—it is inflamed. At first it contains fluid blood, but in a day or two it becomes filled with solid matter; and if you slit open such an inflamed pile, you find a solid lump of dark coloured fibrine. If you slit open an inflamed varicose cluster in the leg, under these circumstances, you will find that the cavity is filled up in like manner with coagulated blood. I mention this, that you may recollect what takes place in these inflamed veins, not recommending the practice, which is quite wrong, as I shall explain by-and-by. The effect of such inflammation is to give the patient a good deal of pain at the time, but he is benefitted by it afterwards. The coagulum fills up the vein, the vein becomes obliterated, and the varicose cluster is cured: others may form, but this one is cured. So in an inflamed pile, other piles may form, but the first is cured, and never troubles the patient afterwards. By degrees the inflammation subsides, the coagulum becomes gradually absorbed; as the absorption proceeds, the sides of the vein approximate, and the cavity is obliterated.

In old cases of varicose veins, you will frequently find the skin become inflamed—that is, it will look red, and be very irritable and tender. Sometimes you find the cuticle as it were abraded, and an ichorous discharge takes place from the red cutis. In some cases the whole of the skin of the leg is in this condition. In others there is a chronic inflammation of the cellular membrane. There is effusion of serum into it, and the limb becomes cedematous. When there is disease of the heart, preventing the due passage of the blood through its cavities, the fluid part of the blood is liable to escape from the capillary vessels, and thus you have anasarca of

the legs. But the swelling which takes place in varicose veins does not exactly correspond to anasarca connected with disease of the heart. It is the result of an inflammatory action in the cellular membrane; the fluid has a more distinctly serous character. If you puncture the parts with a needle, the fluid being of greater consistence, does not flow out so rapidly as the thinner fluid escapes after puncture in the case of anasarca.

The inflammation of the skin, and the inflammation of the cellular membrane, in these cases correspond with each other. There is an exudation of serum in one case from the surface of the skin, and in the other from that of the inflamed cellular membrane. These inflammations seem to correspond with those which we meet with in other cases of venous congestion.

But in some instances you find inflammation taking place of a different kind, in the cellular membrane, immediately surrounding the varicose cluster. The cellular membrane becomes infiltrated with coagulated lymph, and then the varicose cluster is, as it were, imbedded in a considerable mass of indurated substance. At first you would suppose that the veins there are obliterated, but they are not. You have a deposit of lymph on the outside, and the blood remains quite fluid. If you put your finger on the hard lump, the course of the vein is readily distinguished by the fluidity of the blood. You feel the fluid blood passing in an open channel, as it were, through a hard or gristly mass. Where there is this deposit of lymph in the cellular membrane round the vein, the skin becomes inflamed, and it may give rise to a troublesome ulcer.

But still, a varicose ulcer does not generally begin in this manner. Usually, the skin being distended at some point, a scab forms upon it. Then the scab comes off, there is an ulcer, and the ulcer spreads. The varicose ulcer, in most instances, begins about the inner ankle; but it may occur, as in the patient whose case is now before us, in other parts of the leg.

Varicose ulcers, in most cases, have a well-marked character, for which, however, you are not at this time to look in this patient, who has been confined to her bed for nearly a week. For the true character of varicose ulcers, you must look at a patient's legs who has been walking about up the time of your seeing her. Varicose ulcers are inclined to assume an oval form, the long diameter of the oval extending in the course of the vein upwards and downwards. These ulcers are generally nearly on a level with the surface of the surrounding skin. The surface of them is dark coloured when the patient is erect, and when the small veins are filled with

blood; but when the patient lies down, the surface becomes florid. The change takes place very speedily from dark to florid, and from florid to dark. The skin, and the margin of the ulcer, are generally of a dingy-red colour, and partly deprived of the cuticle, so that it is difficult to say where the latter terminates and the ulcer begins. These ulcers are generally very irritable and painful, and sometimes are disposed to bleed.

These are the principal circumstances that I have to notice respecting the history of varicose veins of the legs; and now I shall offer to you some observations respecting the treatment to be employed.

Why is it that the superficial veins enlarge, and not the others? Because, as I have already explained, the deep-seated veins have pressure made upon them on every side, but the superficial veins have not. The first thing for you to consider in the treatment is, whether you cannot put the superficial veins, which are dilated and varicose, under the same circumstances with the deep-seated veins which are uniformly supported. This may be accomplished by applying a bandage to the leg. And what kind of bandage? In many cases you may apply merely a partial bandage of adhesive plaster, which will answer the purpose perfectly, giving the patient scarcely any inconvenience. Where the disease is of limited extent—where, for instance, there are only two or three varicose clusters, of small size—you need not trouble the patient with a complete bandage for the whole leg. Have some stripes of adhesive plaster, three or four inches long, according to circumstances, and one inch or an inch and a half wide. First of all, let the patient stand erect, that you may ascertain exactly where the varicose clusters are situated. Having marked the place, let the patient recline and let the foot be raised, so that the blood may run down, and the varix become completely empty. Observe, that the heel ought to be the highest part of the whole person. Then you put on one of the pieces of adhesive plaster across the varicose vessels, and afterwards apply the others in the same manner, drawing up the skin under them, and taking care that the plaster is not thrown into wrinkles or folds. These plasters being applied when the veins are empty, and being strained on the skin beneath, when the patient stands the veins are prevented swelling. In a great many cases you will find that this is sufficient to give all the support required, and perhaps this is all that the patient needs for the whole of his life. A lady consulted me, some years ago, with two or three varicose clusters on the inner ankle and on the back of the leg, but with no varicose veins of any consequence elsewhere. I

put on some pieces of plaster in the manner which I have described. I mention this case only for this reason—that I recommended the treatment seven or eight years ago, and that lately, when she came to London to consult me on another disease, she told me that she had worn the plaster up to this time, and that it had given her complete relief; she had never had occasion for any thing else. But when the veins of the leg are extensively varicose, this compression will not be sufficient, and then you must apply a bandage for the whole leg. There are different kinds of bandages, and sometimes one sort will answer best, and sometimes another. You may use a common roller of coarse unbleached calico, such as we use in the hospital. In some persons you will find a flannel roller more convenient; at any rate, the patient can apply it better for himself. In private practice I frequently recommend a bandage which is made of stocking web. This is a very nice bandage, and very convenient, as the patient can more easily apply it for himself: there is not the dexterity necessary which is required in the application of a common roller. But it will not do for hospital practice, because the bandage is good for nothing after it has been three or four times washed, and because it is too expensive for the lower class of persons.

I must here make a few observations respecting the application of a roller. A bandage should be applied in the morning before a patient goes about, but it need not be worn in the night when the patient lies down. The bandage should begin at the toe, and go up the leg; and you should take care so to apply it as to support the heel. It should be so adapted to the limb as to make uniform and moderate pressure. The pressure should be as nearly as possible equal throughout. Especially it ought not to be tighter above than it is below, for in that case the veins below, where the pressure is least, must necessarily swell. A tight garter increases varicose veins; and the patient ought to be told not to wear a garter at all, but to loop up his stocking. A bandage which is tighter above than below corresponds to a tight garter. But some persons cannot well apply a bandage for themselves, and for them you may prescribe a laced stocking, which is in many respects very convenient. Patients who are awkward in applying a bandage may manage the laced stocking very well for themselves. Laced stockings are made of various materials. The Chinese manufacture a calico called *nauquin*, which is a very good material for the purpose. Some laced stockings are now made partly of Indian rubber cloth, so that they are elastic. An ingenious artist in Jermyn-street makes a laced stocking of

spiral wire, like the springs of braces, but of very fine texture, included within folds of leather or something else. Whether you use spiral wire, or Indian rubber, it is not necessary that the whole of the stocking should be made of the elastic substance; you only want elasticity in a part of the circumference. In most cases I find the Indian rubber cloth to be the best of these elastic materials. Patients complain of the elastic wire cloth being very hot, and besides, if any thing, it makes rather too much pressure. Indian rubber cloth, however, is not very well adapted for hot weather, as the cloth gives way so, that there is not a sufficient support, and hence it does not answer so well as common calico or nauquin in hot climates. However, you will find that each kind of laced stocking has its advantages in particular cases.

So much as to the general treatment of varicose veins; but now we are to consider their treatment under peculiar circumstances. Let us suppose, then, that you are called to a patient in whom there is a varicose cluster of veins in a state of inflammation. There is a great deal of tenderness in the part, and perhaps some fever. The first thing you have to do is to keep the patient in bed, in the horizontal posture, so as to keep the veins emptied of their blood. Then, if there be much inflammation, and the patient suffers a good deal of pain, you may apply leeches; but do not apply them immediately over the veins: they should be applied higher up on the leg, on the sound skin. The biting of a leech over an inflamed vein will give the patient a good deal of pain, and the bite will be difficult to heal. If you apply it on the sound skin in the thigh, or the upper part of the leg, you will relieve the varicose veins just as much as if you had applied it upon them, without giving the patient pain at the time or any trouble afterwards. You may then apply to the inflamed varix a compress wet with spirituous lotion, unless the pain be very great, and then you may use poultices and fomentations instead.

When inflamed varicose veins are distended with coagulum, it used to be the practice formerly to slit open the vein, and turn out the coagulum, but it is not the practice that I should recommend. It is, in fact, very bad practice, and in order to impress this observation the more upon your minds, I will mention a particular case, which I found this morning in looking over one of my old case books. It occurred upwards of twenty years ago. A patient was admitted into the hospital with two or three large clusters of varicose veins. They were all in a state of inflammation; the upper one was the most inflamed.

The patient said that she had had the disease for some years, but that about a week before her admission she had stood for a long time upon a cold stone floor, on a cold damp day. She went to bed, and had a shivering, which was followed by fever, and then this attack of inflammation of the veins took place. I could feel that the blood had become coagulated. I opened the upper varix and let out the coagulum; but the varices below were treated with cold lotion, or in some other simple way. Under this treatment the inflammation very soon subsided in the varicose clusters below, the absorption of coagulated blood began to take place, and the clusters were cured. But observe what happened in the cluster that I had punctured. The puncture became an ulcer, which would not heal, but became very troublesome. At the end of six weeks when the other clusters were well, there was a nasty sore here. I was obliged to make a slough with caustic potash, which I suppose destroyed the remains of the vein which had been opened. The slough came away, the sore assumed a healthy character, and got well, but certainly the patient would have been well some six or eight weeks sooner, if I had pursued the same practice with the upper varicose cluster which I adopted with the lower ones.

The treatment of these clusters of inflamed varicose veins should be just this:—lay the patient in bed; put a cold lotion on the part, or fomentation and poultices if you find these to be more comfortable to the patient; administer purgatives according to circumstances; and if there be much inflammation, but not otherwise, apply leeches to the sound parts above. The result will be, that the veins of the inflamed varix will become obliterated, and the varix will be cured.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Oct. 22, 1837.

R. QUAIN, ESQ., IN THE CHAIR.

Rare Case of Fracture of the Humerus—Alum to Wounds received in Dissection.

THIS was the first meeting of the Society for the session 1837-38. After the usual routine business of nominating members to fill the offices of President, Vice-President, and Committee, for the ensuing year,

Mr. HALE THOMPSON related the following case, which had recently occurred

at the Westminster Hospital. A man was admitted, having received a severe blow on the humerus; and on examination there was every evidence of dislocation having taken place downwards and forwards, under the pectoralis major. It was apparently reduced; but on his being seen the next day, all the original marks of dislocation were present; and on a more careful examination it was discovered that the humerus was split from its head down one-third of its shaft, the split portions resembling the letter V: one portion remaining in the glenoid cavity, the other portion being under the tendon of the pectoral muscle, external to the joint. All attempts at retaining the two divisions of the bone in the glenoid cavity had failed, and Mr. Thompson gave it as his opinion that the man would still have a useful joint, unaccompanied, however, with that perfect freedom of motion which is present in its normal condition.

Mr. COSTELLO remarked that the case was an exceedingly rare one; and a long discussion ensued as to the structure which would fill up the triangular space between the split portions of bone. It was generally considered that it would be osseous in its texture.

Dr. JAMES JOHNSON observed, that as the dissecting season had now commenced, he would draw the attention of the Society to a circumstance mentioned by Dr. Macartney, of Dublin, at the recent meeting at Liverpool. It was to the effect, that a saturated solution of alum, applied for two or three days to a dissection-wound, would prevent any abnormal or dangerous effects occurring from it. He (Dr. M.) had never suffered since he had employed the remedy himself, nor had any of his pupils. He supposed that the intensely astringent power of the remedy constricted the absorbents and vessels of the part, and prevented their taking up any of the poisonous matter into the system.

Mr. HALE THOMPSON remarked, that the late Mr. Brookes always employed a similar preparation himself after receiving a wound in dissection.

Mr. JOHN GREGORY SMITH, after observing that wounds received from dissecting those who had recently died of puerperal peritonitis were generally the most severe, remarked that Mr. Dermott supposed that the injection of saline fluids into the vessels prevented many of the dangerous consequences occurring after receiving a dissecting-wound, as he had frequently seen among his own pupils.

The usual hour having arrived, the Society adjourned.

PHYSICAL SOCIETY, GUY'S
HOSPITAL,

October 21, 1837.

MR. CHAPMAN IN THE CHAIR.

Effect of Posture on the Pulse.

DR. GUY read some short observations on the effect produced by change of posture on the pulse. After stating that the researches hitherto made were incomplete, and that much scope was still left to inquiry, Dr. Guy proceeded to detail the results established by more numerous and more varied experiments than had yet been made. The following short propositions give a connected view of the results established by former observers, and those to which Dr. G.'s own experiments have conducted him:—

1. The effect produced by change of posture on the pulse, is, in both sexes and at all ages, considerable.

2. The difference between the erect and sitting postures is much greater than between the sitting and recumbent postures; being in men more than twice as great, and in females more than ten times as great.

3. The exceptions to the general rule are numerous; and assuming the pulse of healthy males as the standard to which that of females is to be compared, there are thirty-eight exceptions in a hundred in males, and sixty in a hundred in females.

4. The extremes are very remote from the mean results. Thus the difference between standing and sitting may be as high as a third and as low as $\frac{1}{15}$ of the number of pulses in the erect position; between sitting and lying, as high as a fourth and as low as $\frac{1}{3}$ of the number of pulses in the sitting posture; and between standing and lying, the difference may be little less than $\frac{1}{2}$, and as little as $\frac{1}{15}$ of the number of pulses in the erect position.

The following propositions relate to the difference between the pulse of males and that of females:—

1. The pulse of females is much more frequent than that of males.

2. Change of posture has much less effect on the pulse of females than on that of males.

3. The exceptions to the general rule are much more numerous in females than in males.

4. Of these exceptions, the most remarkable are those in which the pulse is more frequent in the recumbent than in the sitting posture.

The following general law, now stated for the first time, is important:—

In males (and probably in females too), the effect of change of posture varies directly as the frequency of the pulse.

The next proposition refers to the cause

of the effect produced by change of posture.

The effect produced by change of posture on the pulse is due to muscular contraction.

Dr. GUY concluded his observations by stating the following general law:—

Muscular contraction, whether employed to change the position of the body or to maintain it in the same position, accelerates the pulse; and the effects of change of posture form merely a particular case of this general law.

The number of experiments from which the above averages are formed, is 160 experiments on healthy males, whose average age was twenty-four years, and 50 on healthy females, whose average was twenty-eight years. All the persons experimented on were in a state of rest, unexcited either by food or exercise.

At the conclusion of Dr. GUY's paper, Mr. GORHAM stated the results of some experiments made by himself on the pulses of infants. These remarks, though irrelevant to the paper, were valuable, inasmuch as they showed the average amount of pulses in children at different ages, which were as follows:—

	Mean Pulses.
From birth to one day old	123
From one day to one week old . .	128
" one week to one month . .	135
" one month to five months, .	149
" five months to two years . .	130
" two years to four years . .	112
" four years to ten years . .	108

The discussion on Dr. GUY's paper was ably sustained by Messrs. Dendy, Iliff, Blenkarn, Hilton, Gaslee, &c.

Dr. GUY, in reply, stated that his observations did not yet admit of practical application, but must be considered as preparatory to the investigation of diseased conditions. Statistics formed the closest approximation to certainty, of which the science of medicine was capable. They did for probability what mathematics did for demonstration; and the objections urged against them affected their application only—their intrinsic value remained the same. In the course of the discussion, Dr. G. vindicated his claim to originality, by comparing his experiments with those of Drs. Knox and Graves; and stated that others had only surmised, while he had proved, that muscular contraction was the cause of the difference in pulses in different positions.

The thanks of the Society were voted to Dr. GUY, for his valuable communication, and the meeting adjourned.

At the next meeting, November 4th, Dr. HUGHES in the chair, Dr. ASHWELL will read a paper on Haemorrhage from the unimpregnated Uterus, associated with hard Tumors.

OF

DRUGS ON SALE IN THE ENGLISH MARKET,

With their Prices and several Duties.

(From the Official Returns up to Tuesday, October 22, 1837.)

Hydrophobia.

In the case of hydrophobia, the boy had been bitten about two months prior to the occurrence of the disease, by a dog; and it appears that the animal was killed soon after. The boy was taken to a druggist's, and the part, according to the statement of the mother, was freely rubbed with nitric acid. The mother brought the child to the hospital two days after, and, as there appeared some doubt as to the condition of the dog, and as the acid had been freely employed, the parts being in a state of inflammation, it was deemed prudent not to meddle with it further. A poultice was ordered, and the child speedily recovered. The disease, in its access and progress, presented nothing unusual. Immediately on his admission the parts were excised, not with any view of arresting the disease by the mere excision, but in order that a free absorbing surface might be presented for the introduction of remedies. The treatment consisted in the application of the extract of belladonna to the arm; and one grain of the same remedy, with three of calomel, were administered by the mouth every hour. The symptoms ap-

peared alleviated at first; but in about six hours he became rapidly worse, and died in about thirty hours after the establishment of the disease.

The post-mortem examination discovered nothing more than is ordinarily met with in such cases.

LITERARY NOTICE.

NEW WORK ON MATERIA MEDICA.

Mr. Pereira has in the press, and will speedily publish, "Elements of Materia Medica and Therapeutics."

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Oct. 26, 1837.

George Mass, Whitby, Lincolnshire.—Augustus Paul, Exeter.—Thos. Harper, Plymouth.—Henry Letheby, Plymouth.—Thomas Griffiths.—Charles Chapman.—James George Atkinson, Wakefield, Yorkshire.—Alfred Maeta, Norwich.—Jas. Pearson, Langshaw, Lancaster.—Robert Brookes, London.—Peter Hulme Edge, Salford.—James Barrington Prowse, Bristol.—John Bubbers Mather, London.—William Thomas Bowler, Warsop.

LECTURES

ON THE

PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE VI.

Physical Examination of the Chest (continued)

—Acoustic properties of the Chest tested by Percussion—Causes of the sound of Percussion—Modes of Percussion; immediate and mediate—Varieties of the Sound in different Regions; in different states of Respiration—Practice of Percussion—Acoustic properties of the Lungs, manifested by the motions of Respiration—Sounds of Respiration, Inspiration, Expiration—Tracheal, Bronchial, and Vesicular Sounds—Varieties of the Sounds; Puerile Respiration, &c.—Duration of the sound of Respiration, &c.

WE have now, then, to consider the acoustic properties of the chest and its organs. We have explored these parts in their relations to sight and touch, and we have next to examine them in relation to sound, which we now know to be merely a kind of resisted motion.

Well, as we tried the sonorous properties of metal and of wood, by striking them, and observing the character of the resulting sound, so we strike the chest to judge of the nature and condition of its materials. The practice of percussion, as a mode of diagnosis, we owe to Avenbrug-

ger. We will first inquire into the principles of this process. You hear that the chest, when struck abruptly with the ends of the fingers, gives a rather deep, and not very short sound; which implies that the vibrations are not quick, and that they do not instantly cease. When I strike in the same manner on the thigh, there is a very different sound—a short dull tap, implying that the vibrations do not continue. I get the same dead tap when I strike that part of the chest in which the liver lies; but you may observe, by referring to the diagrams, that those parts of the chest under which the lungs are, all yield more or less of the deep hollow sound.

Let us examine a little more into the seat of this sound. Is it in the air, or in the solids of the chest? We will first try the properties of sounds produced in the air of hollow bodies. Here is an open India rubber bottle, which gives, when I tap on it, a hollow sound. But if I close its mouth with my finger, you hear how the sound is changed. Try this with the chest: I close the glottis whilst I strike my chest; it does not sensibly alter the note. Again, the sound in the air of hollow bodies is deep in proportion to their size: remark how much deeper the tone of this large bottle is than that of the little one. Try this with the chest: by enlarging and diminishing its hollow by inspiration and expiration, the sound on percussion remains much the same, except that the extremes of inspiration and expiration slightly raise it; whereas, were the sound produced in the air within, the increase of this air should uniformly lower the sound, and the diminution raise it.

As it is not, then, the air that sounds on percussion, it must be the solids; and observe how the solid construction of the chest favours its vibrations. Here are a set of membranes, thin muscles, and integuments, strained on an elastic framework of bone and cartilage, and free to

vibrate so long as the organs within do not check their motions. Let us find something familiar to illustrate this; my hat will do very well. The crown of this hat is free to vibrate, and gives a good hollow sound when struck. I put into it this handkerchief, which, when loose, may serve to represent the air filled to sue of the lung. It still sounds well, because the handkerchief does not check the vibrations. But when I bring my hand in contact with the crown inside, and then strike on the outside, you perceive the sound is rendered short and dull, because the vibrations are stopped by the solid within. Suppose I were to fill my hat with water (for I am not going to do it; I won't try its *water-proof* so far); this, too, would check the vibrations, and you would have no sound on percussion but a short dead tap.

It is just so with the chest. It is in itself more or less free to vibrate; but it receives the character of its vibrations from the organs underneath, which return them, or check them, according to the density of these organs. Thus you find, where the lungs lie, the chest sounds deep and clear; but here, below the sixth rib on the right side, where we come over the liver, or here, to the left of the lower part of the sternum, over the heart, the sound is short and dull, the vibrations being checked by these soft solid organs beneath. So also you can at once perceive that morbid changes of the organs, such as condensation of the lung by disease, or the pouring out of serum into the pleura, would in a similar way arrest the vibrations, and render the sound dull in those parts of the chest where these changes occur. On the other hand, suppose changes of an opposite kind to take place, such as dilatation of the air-cells of the lung, or an effusion of air into the pleural sac, the walls of the chest will then have under them an increased spring, which will make them vibrate on percussion even more strongly than usual, and yield a clearer sound.

These illustrations are enough to shew the general principles of the acoustic examination of the chest by percussion. It is a test of the density and elasticity of the materials within the chest: as diseases alter these qualities, so will they alter the sound on percussion, which may thus announce their presence. A few more considerations will help us to some useful practical applications of these principles.

As we have seen that the walls of the chest give the sound which we hear on striking the chest, so it is plain that they must be sufficiently tense and elastic to vibrate on being struck. The chests of some persons are so loosely put together, and so flaccid, that they give but little sound, although the organs within are

quite healthy. In others, again, there is such a mass of fat and loose integument on the chest, that the walls are completely muffled by it, and they sound but little on percussion. The same difficulty occurs in most cases in certain regions, where muscles of considerable thickness, or the mammae in females, lie on the walls. In other cases, again, the walls of the chest are so drawn in by contracted adhesions, that they are not free to vibrate, and give a dull sound, although the lungs within them may be comparatively healthy. In all these cases we must give to the part struck the equal tension which is wanting, by pressing on it a small piece of some firmly elastic body, such as wood, ivory, stiff India rubber, or the like. You can get plenty of sound by striking this; and if it be firmly applied to the chest, the density of the contents within will modify this sound, just as it modifies that of percussion of the naked walls of the chest. You perceive that the sound which I get on striking on this little plate of ivory pressed on my chest, is the same in character as that which I get by striking the chest itself, only it is louder; and as percussion on it gives no pain, I can strike with force sufficient to make the vibrations reach the interior, through any thickness of fat or muscle. By this means we can get at the sonorous qualities of the thoracic viscera through the scapulae and muscles of the back, and through fat or oedematous integuments of any thickness. In this way, too, we can get the resonance, or sonorous quality, of any part of the abdomen. In some regions, as in the right iliac and left hypochondriac, the gaseous distension of the colon and stomach often stretches the solids over them enough to make these solids yield a drum-like sound when struck; but the pressure of a solid plate on them will always give these and other regions such a tension, that a stroke on its surface will be modified by what lies underneath.

We owe this method of *mediate* percussion to M. Piorry, who calls this percussion-plate a *pleximeter*; and it is so much better than immediate percussion, that it is now generally preferred. There is, however, an improvement on it, which is, I believe, due to an Englishman, Dr. Skerrett; this is, to substitute for a pleximeter the fingers of the left hand. I need say little to recommend this method of percussion; if you do not already know it, you will soon find out how convenient and *handy* it is, how nicely you can fit the fingers to the inequalities of the chest, sometimes singly, sometimes together; sometimes with their palmar surface outermost to strike on, but generally with this applied to the chest and their backs to strike on, and so forth, as I will shew you at a future

lecture, when I will give you practical demonstrations of all the different methods of examination.

Now that we know how to percuss the chest so as to make it sound, let us see how this sound in different parts ought to be affected by the organs within; and here, again, you see we have need of the topographical knowledge that I said was necessary for a correct physical examination of the chest. These diagrams will assist us; and for the different sounds on percussion in different regions, I must refer you to the table and plates at the end of my work on Diseases of the Chest.

You see here, coloured light pink, the shape of the lungs seen through the parietes; and over the whole of that you get, more or less, the resonant pulmonary sound on percussion. In all the upper parts of the chest, before, behind, and at the sides, this sound is pure and unmixed, and equal on both sides, because there is nothing but lung underneath, as you see represented in the drawing by the unmixed pink. But between the fourth and fifth rib on the right side, you see this pink begins to get a shade of purple from the liver, that here rises into the central part of the chest beyond the lung; and this purple tint becomes darker and darker as the lung is thinner, and the liver approaches the surface, until we come to the margin of the lungs, where the light pink of the lung quite ceases, and the unveiled purple of the liver denotes that this organ is in contact with the walls of the chest. Now, is there any mixture of the lung and liver sounds where we see this blending of their tints in the diagram? I say yes; and I will give you the proof of it when we have a living subject before us. As soon as we get down to the upper level of the liver there is a very slight deadening of the pulmonary sound on percussion; and this deadening increases down to the margin of the lungs, below which it is entirely changed into the dead hepatic sound. You see by this that the stroke of percussion reaches a considerable depth, to organs an inch or more from the walls; and whatever it reaches may modify its sound. This suggests to us, that by varying the force of the stroke, we may make the impulse of percussion reach to different depths, and derive the character of its sound from the superficial or the deep-seated organs, as we will. So, after some practice, you will find that where the lung overlaps the liver, *strong* percussion will give you a shorter, deader sound, than *gentle* percussion. Strong percussion receives the character of its sound from the liver as well as the lung; whilst gentle percussion, as by *filliping* with the finger and thumb, does not pass beyond the thin

layer of the lung, and gives still the pulmonary sound.

Let us look to the left side of the chest. Here, at the sternum, about its junction with the third rib, we see the light pink of the lungs taking a scarlet tinge from the heart, and you can see its shape blushing through the lungs down to between the fifth and sixth ribs, about an inch below and before the left nipple, where, from the brightness of the colour, you may see that the apex of the heart approaches very near the walls of the chest; and to the left of the lower third of the sternum, its body is in contact with them. So there is a mixture of dull and clear sounds on percussion in these situations, although, from the movements of the heart and lungs, the spots where one shades into the other are not fixed. You see, in the lower part of the left side, a yellow tinge, which rises, in a faint degree, as high as the mammilla. This indicates the vicinity of the stomach, with its clear drum-like sound, which becomes mixed with the pulmonary sound in this region, but to a degree varying according to the quantity of air contained in the stomach. Here, again, is the spleen, which, as you see by this blue tint, affects the sound of the small portion of the lateral lobe of the left lung.

Now you must not forget that the motions of respiration may produce changes in the character and relative positions of some of these sounds. Inspiration, as it enlarges the lung, renders the pulmonary sound clearer, and extends it over every part of the heart, and over a considerable portion of the liver. As we found that the complete and equal enlargement and contraction of the chest, as seen and felt, are signs of the free condition of the respiratory organs, so the sound on percussion becomes an additional sign of the healthy action in proportion as the clear pulmonary sound is extended at each expansion of the chest. Observe, when after a full expiration I strike my chest over the region of the heart, and over the middle region of the liver, the sound is dull, and scarcely pulmonary. I take in a full breath; and now you hear how clear it sounds all over these regions. Percussion is a test, therefore, not only of the *statical* condition of the lung, but of the *dynamical* state also. This point is not enough attended to by auscultators, and yet the neglect of it not only would deprive us of additional signs, but would tend to render deceptive the results of statical percussion. For example, in judging of the goodness of the sound on percussion, we generally compare the sounds on the two sides of the chest, or in two parts of the same side where naturally the structures and sounds

are the same: but if we do not attend to the movements of respiration, we may strike one part when the chest is contracted, and the other when it is full, and obtain results which differ from this cause only, and not from any internal change. In practising comparative percussion, therefore, in cases requiring delicacy, you should desire the patient to hold his breath for an instant whilst the comparison is made, and it is often useful to try the sounds when the chest is expanded to its utmost, when it is contracted, and in the intermediate states.

It would be going out of my order to describe the varieties in percussion from special diseases, but an illustration or two more will enliven the subject.

The indurations of the upper lobes of the lung in the early stages of phthisis are often small, and so scattered through its substance, that they scarcely affect the sound on percussion; but by a full expiration they are brought closer together, and if more on one side than the other, they may then more sensibly deaden the sound on that side, especially if gentle mediate percussion be used below the clavicles, and not on a very small surface. Again, the indurations, especially if of some standing, tend to restrain the lung from its full expansion, and if there be a difference on the two sides, it thus may be detected only on a full inspiration. In the disease called emphysema of the lungs, the air-cells are permanently dilated; they contain an unusual quantity of air, which expiration cannot expel; this may be detected by percussion as a dynamical test; the regions of the heart and upper part of the liver being covered by the permanently distended lung, even after expiration, give a clear sound. There is one point more to notice respecting percussion at the extremes of the respiratory act. Full inspiration makes the sound clearer; full expiration, the contrary: but they both raise the tone a little; they render its pitch higher. Why is this? For the simplest reason in the world; both actions *tighten the drum*; they strain walls of the chest, and render their vibrations quicker, and therefore the sound higher. It requires a musical ear to detect these differences, and I do not think it useful to dwell further on them.

I think I need add no more on the principles of percussion; but to those who have not practised it, I would say, do so without delay, and on every opportunity; for, like every other art in which our senses are exercised, there must be practice to familiarize you with the phenomena, and the mode of obtaining them. I trust that the principles which I have given you will guide and assist you in this

practice. 'There is no better way of trying to get this familiarity than by percussing your own chests. A few minutes when you rise in the morning occasionally spent in studying before the glass the outward marks and different sounds of the regions and their corresponding organs, will go far to instruct you in the practice of percussion, and in the character of the sounds in health; and the awkwardness and annoyance inseparable from first attempts will be felt only by the person who is least likely to complain of them.

You will soon find even in these trials that some art is required even in mediate percussion, which is the easiest. The finger or fingers of the left hand should be closely pressed on the walls of the chest, and if the object be comparison of the two sides, they should be placed on corresponding parts, whether between the ribs, along them, or across them. Take care, too, that the mode of striking be the same, whether you strike with one or several fingers, with their tops (in which case you must keep your nails pretty closely cut), or the flat of the last phalanx, or with the knuckles; each of which modes is sometimes preferable. I often find *flipping* with the middle finger and thumb [thus] give more uniform and delicate results: especially when the patient is in an inconvenient position, or suffers from tenderness of the walls of the chest, this is the best mode for abdominal percussion. In doubtful cases, however, various modes must be tried and practised, as I have before remarked, with due relation to the period of the respiratory movements. There are a few cases in which a little plate of thin wood or ivory, as recommended by M. Piorry, may be used with advantage; it should be covered with soft leather, to prevent the clack of the fingers on its surface. In M. Piorry's works "*De la Percussion Mediate*," and "*Du Procédé Opératoire*," &c. you will find some useful descriptions of the varieties of sound obtained by this instrument, but he much exaggerates its advantages. If you wish to know more of the principles of percussion, you may consult a paper of mine, published in the *MEDICAL GAZETTE* of January, 1837.

Now let us inquire into other modes of producing sounds in the chest, which may prove acoustic signs of the condition of the organs within. There are the motions of respiration, will not they produce sound? The contractions and relaxations of the muscles of respiration are in general too gentle to cause sound; but when forcible or sudden, they will sometimes occasion a sound of tightening, of the kind called muscular sound. This is of no con-

sequence, and gives no signs. But there are the internal motions, and the attendant passage of air to and fro in the lungs; these produce sounds, and inasmuch as this passage of the air is the great object of respiration, we may expect to find in these sounds signs of the manner in which this object is accomplished. These, and most of the other acoustic phenomena of the motions of the chest, were first discovered and described by Laennec, who may well be considered the father of the art of auscultation. We shall endeavour so to illustrate and extend this art, by the aid of physical and physiological science, that we may be enabled to deduce respectively from the phenomena the condition of the organs, and from any known condition of the organs, the phenomena which it would produce.

The air enters the lungs by atmospheric pressure, to fill the increased space made in the chest by the action of the muscles of inspiration. On its way to the most expandible parts of the lung, the fine tubes and cells, it strikes against the sides and angles of the trachea and its ramifications, with force sufficient to produce a particular hollow blowing sound. You may hear this on applying the ear to the fore part of the neck, or at the top of the sternum. As the current of air becomes subdivided and spread in the small bronchi, it loses a part of its velocity, and the sound becomes of a more diffused and less hollow character; it is more like the sighing of a gentle breeze among the leaves of trees, and in passing into the cellular terminations, all of the hollow or tubular sound is lost, as you may find on applying your ear to most parts of the chest. This sound may partly depend also on the opening and stretching of the tubes and cells. Where inspiration ceases, expiration begins, and a portion of air is pressed out of the cells and small tubes by the collapse of the walls of the chest, and by the contracting properties of the pulmonary tissues. Now, remark the difference between inspiration and expiration. In inspiration the air is the moving body, and rushing through the tubes distends the passive lung. In expiration the lung is the moving body, and by its contraction (backed by external pressure) drives before it the passive air. In either case there is a pressure exerted between the air and the interior of the cells, and doubtless this proves the means of assisting the chemical changes that take place. But you can see that there must be a difference between the sounds of inspiration and expiration. In inspiration, air moving with some velocity meets with the resistance of the angles and sides of the tubes and cells which it has to dilate. Here must be sound in the whole passages

of the air, from the nostrils down to the pulmonary cells. In expiration, the motion begins with the lungs, and, the air passively yielding to it, there is not motion or resistance enough to produce sound, until by the converging together of the small tubes, the impelled air is gathered into a current in the larger tubes, where, impinging against their sides with its now acquired velocity, it at length produces sound. These remarks will enable you to perceive, that in natural respiration there are three kinds of sound—*tracheal*, *bronchial*, and *vesicular*. In expiration, at most only two, *bronchial* and *tracheal*. I am not sure who first remarked these differences, which were overlooked by Laennec. They are mentioned by Andral, Louis, and Dr. Cowan, who accredits them to the late Dr. Jackson, a young American student at Paris, whom I knew as an uncommonly zealous and clever observer. They are worth notice, and are plainly produced in the manner which I have explained. We shall say no more at present of the distinctions between these parts of the act of breathing, but class them generally, as Laennec did, as the sounds of respiration.

I have said that the sounds of respiration can be heard on applying the ear to the chest; they are transmitted through the parietes with sufficient distinctness from the parts underneath; and as the healthy sounds vary in these different parts, we may judge of the natural distribution of the tubes by listening to these sounds. Thus we find, in any part of the neck, and at the upper part of the sternum, there is the hollow blowing sound which results from the passage of air to and fro in the trachea, which is therefore called *tracheal* respiration. A little lower down than this, over the space of two or three inches on each side of the top of the sternum, between the scapulae, and sometimes in the axillae, there is the sound called *bronchial* respiration, because its whiffing or tubular character denotes that the sound is produced by the passage of air in the bronchial tubes. Then there is the *vesicular* respiration, which is heard in most other parts of the chest; it is a diffused murmur, caused by the air penetrating through the minutest tubes, and into their numerous vesicles or cells.

Now a question will occur to you (at least I hope it will, that you may be more interested in the answer), how is it that the *bronchial* respiration is heard in comparatively few parts of the chest, when we find bronchial tubes of considerable size in most parts of the lungs, to within an inch or so of their surface? Why is not the sound a mixture of the tubular and vesicular sounds? Just consider that the sound in these tubes must be conducted through

the tissue of the lung to its surface before it can reach the ear; and what sort of a conductor of sound will this tissue be? We found that equality of density or rigidity renders a body a good conductor of sound; but here we have a flaccid tissue, composed of the unequal materials, membrane and air; and sound in traversing an inch of this tissue would have to pass from air to membrane, and membrane to air, thirty or forty times. We saw how a loosely folded cloth stops sound; still more especially does this spongy tissue of the lung arrest all the slighter sounds that are produced in the tubes within it; so that what we hear outside the chest, unless the tubes underneath are of very large size, or very near the surface, is only the vesicular sound of the superficial parts of lung. You may, if you please, take a hint from this, if you want to shut out the noise of a street, or of a noisy neighbour, or if you wish to keep your own noises to yourself, you will have on the shutters, or in the walls, some loose porous body, such as wool, cotton, shavings, or the like, which will effectually arrest and choke the vibrations in their passage, and will in a measure isolate you with regard to sounds.

And now mark an important corollary to our last proposition. As this arrest of the sounds of the interior depends on the light spongy structure of the lung, so any disease increasing the density of that structure will increase its conducting power, and enable it to transmit the sounds. Hence we find that a great increase of solid or liquid in the lung, as in pneumonia or tuberculous deposit, or the compression of its superficial parts by a moderate quantity of liquid in the pleura, as in a recent pleurisy, will often not only diminish the vesicular murmur in consequence of the obstructed state of the cells, but will add also a bronchial or tubular sound of breathing in those parts where naturally the respiration is purely vesicular.

Now, I think, we understand the ordinary sounds of respiration; let us attend to some varieties of them. As these sounds depend on the resisted motion of the air, so they will vary according to the velocity of that motion, and the degree of resistance to it, they will be loud when the air passes in and out forcibly and quickly, and low when it passes gently and slowly. So when you are listening to a person's breathing, it may be scarcely audible at its ordinary rate, but if he breathe quick and short, it will be distinct enough. Taking a long breath may not answer the same purpose, for although much air is thus taken in, it may not enter with sufficient rapidity to cause the increased sound.

Coughing answers better, for the long inspiration which follows coughing is generally quick also; and it is often useful where the sounds are obscure, to magnify them by this more forcible act. But there is a limit to the power of increasing the sound of respiration by increased effort. If a person tries to breathe very hard and quick, as after violent exertion, the movements of the lungs cannot keep pace with those of the external muscles of respiration, and the air does not freely enter, the sound will be diminished rather than increased.

As we can vary the sound of respiration by varying the act in the same individual, so we find that a difference exists naturally in different individuals: in some, as in many robust adults, you find the ordinary respiratory sound very low and faint; in others, as in children, in nervous females, and in slight irritable persons, you find the sound loud and distinct. In the last cases the respiratory movements are more brisk, and although air may often not be taken in more frequently, or in such great quantity as in the other cases, yet it enters more suddenly, and meets with greater resistance in its passage, so that it must cause more sound. As this loud respiration is commonly met with in children, Laennec called it *puerile* respiration. So, also, by rendering the respiration quicker and more energetic, you may make its sound loud in those cases where it is naturally faint, as by the quick short breathing which I have just mentioned; or better still, by desiring the person to hold his breath for a while; the quick strong inspiration which then follows is noisy enough. Disease will sometimes bring about the same change: thus if a considerable portion of the lungs be obstructed, the force of the act of breathing will be concentrated on the remaining portions, and the air will be carried in and out of them with unwonted energy and noise. Hence Andral terms this partially increased respiration *supplementary*. So also, under some circumstances, without any obstruction, the want of breath may be increased—as it happens during moderate exercise, and in some degree during the process of digestion, and on exposure to cold: here respiration is more energetic, and its sound louder. Further, as the act of breathing depends on a particular impression on the nervous system, so you can easily perceive when this system is preternaturally sensitive, the ordinary impression produces an increased effect; and here, again, the respiration becomes more energetic and noisy. This is the cause of the increased sound of respiration in certain fevers and other diseases where the nervous sensibility is exalted. Lastly, it is pos-

sible, by an external restraint of some parts of the chest, to render the sound of respiration louder in other parts. Thus, if you inclose the abdomen and lower part of the chest in a tight belt (or you may meet with the experiment already prepared in the persons of tight-laced ladies), you will often find the sound of respiration in the upper parts unusually loud; and you see by the heaving of these parts how their motions are increased.

Now you see there may be much variety in the sound of respiration, without disease of the lungs: and, excepting in the case last mentioned, it is where there is a comparative difference in the different parts of the lungs, rather than any absolute difference, that disease of these organs is indicated. Thus, if you find the respiration loud on one side and obscure on the other, or clear in the lower part of the chest and indistinct in the upper, you may well suspect some obstruction to exist in those parts where the sound is obscure; and the nature of that obstruction is then to be tested by percussion and other means.

There is another kind of variety in the respiratory sound that has not been attended to—a variety in its *duration*. In this, as in the other varieties, there are absolute differences in different individuals, and in the same individual under different circumstances; but I shall only notice the comparative differences in the same subject at the same time, which alone constitute signs of disease. We sometimes hear the sound of inspiration on one side distinct and prolonged during the whole inspiratory act; on the other side loud enough at first, but abruptly stopped before the act is complete, and often stopped with a sort of *hic*. This kind of hitch in the sound sometimes reminds me of M. Alexandre, the mimic; imitating the noise of planing, he gives you the idea of meeting with a knot in the wood, by stopping short the noise with a *hic*. So the stop put to the expansion of the lung is often as sudden; and this denotes that the obstruction is then complete. Hepatization of the lower portions of the lung will do this; so will a moveable plug of tough mucus in the bronchial tubes. In other cases, again, we find the circumstances reversed; there is in a part of the lung no sound during the first part of inspiration, but towards its end, when the chest is most expanded, there is a short wheeze. This happens where the bronchial tubes are so far obstructed that air will not pass through them until they are distended by a full inspiration, as in bronchitis. It happens also in pleuritic effusions, which distend the parietes of the chest beyond the medium state of respiration; it is only the *acmé* of inspiration that can then intro-

duce air into the compressed lung, and it is at this period alone that the sound is heard.

I must not detain you now with other morbid varieties of respiration, which will severally come under our notice when we consider the diseases which cause them. There is the *cavernous* respiration, caused by the passage of air in and out of an unnatural hollow or cavity in the lung; and the *amphoric* respiration is where this cavity is so large, that the sound is like blowing into a phial, or into this India rubber bottle.

In the next lecture I will give you a tabular view of these and other varieties of respiration, and of their remarkable accompaniments, the various *rhonchi*, which are produced by an increased resistance to the passage of the air.

LECTURES

ON

RHEUMATISM AND ITS EFFECTS;

By R. MACLEOD, M.D.

Physician to St. George's Hospital.

LECTURE III.

Maniacal Delirium sometimes indicative of Rheumatic Inflammation of the Heart—Cases in illustration.—Immediate effects of Rheumatism on the Pericardium, and on the interior of the Heart; description of the anomalous appearances.—Secondary changes resulting from Rheumatism of the Heart.—Disease of the Valves; Hypertrophy and Dilatation of the Cavities—Signs of these.

I HAVE alluded to the peculiar change in the expression of the patient which usually attends rheumatism of the heart. Now this sometimes goes much farther; it passes into the anxiety of delirium, or the wildness of insanity. This is no new fact; it was referred to by Andral many years ago; was stated in his Gulstonian lectures by Dr. Francis Hawkins; was enlarged upon by Dr. Latham; and more recently, has been especially mentioned by Dr. Watson in one of his published clinical lectures. So far as I know, in all the recorded cases in which rheumatism of the heart has been attended by symptoms of inflammation of the membranes of the brain, the patients have died, and the encephalon has been found intact, or at least without any unequivocal evidence of inflammation. Indeed it is the remarkable fact of no diseased appearances having been found in the part to which the chief

symptoms were referred, which led to the cases being placed on record. I have reason to believe, however, that pericarditis may occur, accompanied by cerebral symptoms of the severest character, and still the patient entirely recover under the persevering use of proper remedies. The following appears to be a case in point:—

Mary Hall, ætat. 27, admitted in the third week of rheumatic fever, January 25, 1836. She made no complaint excepting of the limbs, but her expression was anxious; and on being questioned, she acknowledged that she had some uneasiness in the region of the heart, in which situation pressure between the ribs gave pain. Nothing abnormal in the sounds of the heart, or respiration, could be perceived.

26th.—Makes no complaint, but shrinks from pressure in the region of the heart. On applying the stethoscope to-day, a rubbing sound is distinctly perceived at the left and lower third of the sternum; considerable faintness; much anxiety; *some incoherence*.

27th.—Denies that she has any uneasiness in the chest, but is too incoherent to be trusted as to what she feels. No rubbing sound to be heard, but pulsations heard more obscurely, and as if more distant.

28th.—Constant delirium, with so much restlessness and jactitation, that no satisfactory examination of the heart could be made for several days, during which time it was necessary to put on a strait waistcoat.

On the 4th of February, during a quiet interval, the pulsations of the heart were found to be feeble, distant, and intermittent.

The same examination, and with the same result, on the 5th. The pulse on both days from 100 to 105, feeble and intermittent.

8th.—Calmer. The pulse 100, more steady, but with occasional intermissions. Sounds of the heart again approach the ear, the idea of distance being diminished. No rubbing.

12th and 13th.—A fit each day, of epileptic character, to which it does not appear that she has been subject. Complaints of pain under the left mamma; no change in the character of the sounds.

From this time she gradually recovered, having had no farther recurrence of the symptoms, and the action of the heart having become quiet and natural.

I have nothing to say of the treatment in detail, my present object being only to illustrate the extent to which the functions of the brain may participate in this form of rheumatism. I may state, however, that after the supervention of the heart symptoms, she was bled once generally,

once locally; was blistered on the chest, and took calomel and opium, with purgatives.

Since this lecture was delivered, another case has presented phenomena considerably resembling the preceding.

Thomas Spratt, ætat. 39, of rather intemperate habits, was admitted into St. George's Hospital, September 21st, having laboured under acute rheumatism for three weeks. The attack commenced in the shoulder and side of the face, but soon extended to other parts, particularly the hands and feet, which were swollen and red, while he had all the common symptoms of rheumatic fever. He was bled and purged, and took calomel and opium, without any thing to arrest attention, till the 24th, when he was observed to be incoherent, with much wildness of expression. He was ordered a grain of opium every six hours; and the gums being sore, the calomel was omitted.

25th.—The delirium had increased, so that he was at times quite unmanageable; he had had what was called by the nurse "a fainting fit;" pulse 100, with occasional intermission.

Some, but rather obscure sound of friction, and some degree of bellows sound on applying the stethoscope over the heart. Half a grain of acetate of morphia was given every six hours, and a strait waistcoat put on.

28th.—Delirium continues; puts his hand occasionally to the heart, and on being questioned, says he has pain there; but his answers have been too incoherent since the 24th, to be relied upon. The sounds of the heart are obscure; but some degree of rubbing continues.

The acetate of morphia was increased to half a grain every four, and then every two hours.

30th.—Much quieter; pulse 85; sounds of heart more distinct; rubbing no longer audible; some blowing sound continues.

From this time he gradually recovered; and the sounds of the heart became natural after a time.

In another case admitted under Dr. Chambers during the summer, a patient had furious paroxysms of maniacal delirium; and on examining the body after death, the pericardium bore evidence of very acute and recent inflammation.

I admit that, as in the cases of Hall and Spratt, no opportunity was afforded of examining the brain, so it may be matter of question whether that organ was, or was not, the seat of inflammation. My belief that it was *not*, resulted from my previous knowledge, on the authorities above quoted, that sympathetic disturbance of the brain, of the most violent nature, may take place in carditis,

though there be no organic affection of the encephalon, or at least none which leaves any trace behind. The physical signs left no doubt of the existence of pericarditis, while there was neither heat of scalp, nor injection of the eye, nor intolerance of light, such as is usually met with in inflammation of the membranes of the brain. Again, in a case recorded by M. Andral, there were delirium, convulsive twitchings, tetanic spasms, coma, and paralysis; yet all this was found by the autopsy to have arisen from pericarditis, without a single vestige of disease in the head.

While I readily admit that the assistance to be derived from the stethoscope in general practice has by some been greatly exaggerated, yet here, in such a case as rheumatic fever, with extension of the disease to the heart, producing general symptoms which are obscure, or causing sympathetic affections of a distant organ calculated to draw off the attention from the real seat of the disorganizing process, or perhaps not exciting symptoms any where calculated to raise suspicion—one and all of which conditions I have seen; I say that, under such circumstances, the assistance to be derived from auscultation is paramount; and that he who refuses to make use of it, denies himself the only means we possess of arriving at a correct diagnosis—thus placing in jeopardy the life of his patient, to say nothing of the peril to his own reputation.

But there is another affection of the head, altogether different from the preceding, which, nevertheless, I am inclined to think has been confounded with it—namely, a true inflammation of the brain or its membranes, connected with rheumatism. This, however, in all the cases of it I have ever seen, has arisen in connexion with rheumatism of the synovial membranes, and without any pericarditis. On the other hand, I have never known fibrous rheumatism affect the brain except secondarily (I believe functionally), and after the heart had become implicated.

Rheumatism of the heart, in the great majority of cases, is cured, or so far alleviated that the patient recovers from the primary attack. Unless, however, the treatment has been both energetic and judicious, the organ receives an injury which leads to slowly increasing change in its structure, and thus ultimately to a fatal result. Some, however, are cut off during the first attack, and the appearances which then present themselves are convincing evidences of the nature of the disease. The pericardium is found to have been inflamed, and as regards this membrane I know of no difference which ex-

ists between the changes effected by rheumatic and common inflammation.

The results to which the inflammation has ultimately given rise, are sometimes in description confounded with those which spring directly and immediately from this cause. In a recent case the appearances are striking. On raising the sternum, lymph is sometimes perceived even in the anterior mediastinum. The bag of the pericardium is seen to be inflamed; and here, unlike what I had occasion to mention with respect to rheumatism of the joints, the effects are conspicuous, and the inflammation marked by a greatly increased number of vessels carrying red blood. The pericardium feels pulpy, or fluctuating; and frequently on cutting through it we do not at once expose the heart, but find a layer of lymph intervening, adherent partially or more extensively to both serous surfaces.

But the abnormal appearances are not always limited to the exterior. The valves, especially those on the left side, may be inflamed. Ultimately the change is manifested by their augmented size and thickness; but at this early period, and supposing it to be a first attack, the only thing which may be visible is what might be described as a slight tumefaction at the ostia; looking from the left auricle towards the ventricle, the aperture seems narrowed; and I have seen the portion of the valve where its sides meet in closing, of a flesh-colour, presenting through a magnifying glass the appearance of minute spots, like granulations, with vessels carrying red blood entering them from the interior of the auricle. In the same subject the aortic valves were of a distinctly pink hue to the naked eye, but without any vessels which could be detected even with a glass. There was a point, like a very minute granulation, on the centre of one of them, being apparently the earliest stage of those small bead-like projections which are frequently seen at a more advanced period. M. Chomel has also described the appearance of granulations, varying in size from a pin's head to a millet seed, as occurring in a recent case both on the mitral and aortic valves; the former having unequivocal evidence of its being inflamed afforded by a portion of adherent lymph. In the case to which I have alluded, there was perhaps some narrowing of the aortic orifice, as if the parts around had been slightly tumefied; but this was not so conspicuous as in the auriculo-ventricular aperture. Red vessels could be traced from the surface of the auricle to its valve, but not so with respect to the ventricle. On the right side there was some opacity of the mitral valve, but nothing fur-

ther. The pulmonary valves were healthy. This is the earliest condition in which I have had an opportunity of examining the endo-carditis which accompanies rheumatism—that morbid change in the valves of the heart which ultimately leads to their permanent opacity and thickening, and to various important alterations, not only in the heart, but secondarily in other parts of the body.

In a case which is related in the 5th volume of the Edinburgh Medical and Surgical Journal, the inner surface of the right ventricle is stated to have been inflamed, in a girl who died of rheumatic fever, while both the mitral and tricuspid valves were coated with lymph. In the very few cases, however, which I have seen examined, where death had taken place, in the primary stage of acute rheumatism, the appearance of inflammation has been most conspicuous in the auricles, particularly the left, and at the semilunar valves, particularly the aortic; but without extending into the ventricle. And again, if we are to take opacity and thickening as proofs of preceding inflammation, such appearances in those who die of the secondary consequences of a damaged heart are much more remarkable towards the auricular than the ventricular connexions of the valves common to both cavities; while changes in the semilunar valves, if not strictly limited, are more wont to extend towards the inner surface of the arteries than the ventricles; and more especially as regards the aorta.

The above description applies to the immediate effects of rheumatic inflammation on the textures of the heart; but in our post-mortem examinations we are much more frequently called upon to witness the changes which have been produced by the slow and continued influence which follows the primary injury; and here it will be most convenient to describe what those changes are, before we speak of the signs by which they are indicated.

The lymph which has been effused on the external surface of the heart may, there is reason to believe, disappear under the influence of proper remedies, and the integrity of the viscus be in this respect restored. Indeed it is apparent that the powers of nature, aided by judicious treatment, are much more successful here than as regards the restoration of the lining membrane, where *endo-carditis* has existed; for it is not uncommon to find the valves extensively diseased, in consequence of rheumatism, where the external covering of the heart is little or not at all different from its healthy condition.

The most common morbid appearance of the pericardium, of a permanent nature,

is opacity and thickening—sometimes general, but more commonly in patches. This change is much more conspicuous on the surface of the heart than in the free part of the pericardium, and may be accounted for by portions of lymph, effused during the period of active inflammation, having become organised. It is to be supposed that some degree of thickening of the pericardium attends that condition in which it has been inflamed, and remains subsequently opaque; but the extent to which increase of actual bulk occurs is extremely limited; and wherever there is an opaque patch of perceptible thickness, this may almost invariably be separated from the pericardium by *peeling*, and conveys the idea, when thus examined, rather of a layer or layers of adventitious membrane superimposed, than of interstitial increase of dimension in the pericardium itself. Or if the bag of the pericardium appear thickened, when we come to examine this minutely we shall generally find either that layers of lymph have been effused upon the surface, or that it has been poured out between the fibrous and serous membranes, so as to separate them.

In those cases where the effusion has been more extensive, or the absorbing powers less active, the two surfaces of the pericardium become glued together by the interposed lymph, which speedily assumes an organic form—at first soft, and easily torn, but progressively becoming more dense, till it assume the appearance of a close cellular membrane. Most frequently this union between the pericardial surfaces is general, but occasionally it is partial. In yet rarer cases the adhesions exist only at one or more spots; and sometimes the connecting texture presents the appearance of bands or layers joining the surface of the heart to the bag of the pericardium.

When the parietal pericardium is universally adherent to the surface of the heart, it also frequently forms anormal adhesions externally, particularly if the patient have been subject to repeated attacks of rheumatic fever. In such case the pericardium may be firmly united to all the adjacent parts, as if a quantity of liquid size had been poured in, so as to fill up every interstice, and had then become organized.

There are no symptoms by which the presence of mere thickened patches can ever be detected before death; nor, under ordinary circumstances, can adhesion of the pericardium be convincingly ascertained during the life of the patient. Where the adhesions are partial, it has been supposed that pain or other distressing sensation would be

produced when the individual was placed in such position as to cause any degree of suspension or dragging upon these adventitious ligaments; we should also expect adhesions about the apex of the viscus to disturb its action more than such as are situated at its basis. Louis has given a case, in which the patient was unable to lie on the back, in consequence of a smarting pain in the region of the heart being excited by this posture. On examining the body, a single firm adhesion was found extending along the right ventricle; so that in the supine posture this must have been dragged upon by the heart, and must consequently have put the parietal and cardiac portions of the pericardium on the stretch at these points of union. Dr. Hope has mentioned a "jogging or tumbling" motion of the heart as characteristic of such partial adhesions; but I fear that much remains to be done ere we can speak with confidence of such marks of diagnosis. When the adhesion is universal, so that the heart is, as it were, firmly glued to all the adjacent parts, a certain degree of dragging inwards of the intercostal spaces and epigastric region may be perceived corresponding to the heart's action; at least in some few instances this has appeared to me to be the case; but in others nothing of the kind has been perceptible during life, although on examination after death the pericardium has been found universally adherent.

It seems to be in certain stages and conditions of the thickening caused by lymph becoming organised, that the sound called *creaking of leather*, by the French, occurs; it is one which I believe to be very rare, and to have been mixed up in description with the more common sound of friction.

Important as we must acknowledge these results of pericarditis to be, they are, nevertheless, greatly inferior in frequency, and in their consequent evils, to those changes to which the internal parts of the heart are subject from rheumatic inflammation. The valvular apparatus is that the organization of which undergoes the most remarkable modifications, and leads to the most destructive consequences, both as regards the functions of the heart itself, and the integrity of the general system. With respect to the external lining of the heart, I do not know that one portion of it is decidedly more liable to disease than another; but if I were to be guided by the results of my own experience, I should say that where the inflammation did not extend over the entire pericardium, the anterior portion was more frequently inflamed than the posterior. In regard to the lining membrane, there can be no doubt that the manifestations are greatly more frequent and more severe in the left

than in the right side of the heart. This has been attributed by some to the more stimulating influence of the arterial than venous blood, but it is by no means obvious in what manner this should be productive of disease. On either side the portion of the lining membrane chiefly implicated is that which forms the valves, and considered with reference to rheumatism, the rationale of these parts being most obnoxious to attack is evident enough when we consider the pre-eminently fibrous nature of their structure. In those who have had the heart affected in rheumatism, the most common circumstance is to find both sets of valves of the left side diseased; but if the morbid alteration be limited to one, then the auriculo-ventricular is more apt to shew change of structure than the aortic valves, whereas I think that in valvular disease from other causes the reverse is the case. By much the most common kind of change is more or less of thickening, and this, more especially in the mitral valve, is sometimes accompanied by unequivocal evidence of previous inflammation of the adhesive character, its different portions being frequently more or less united together, or glued to the adjacent surface of the heart. When the auriculo-ventricular valves on either side are opaque and thickening, the participation of the lining membrane beyond them in such change is for the most part much more marked in the auricle than in the ventricle; corresponding to what I have already stated with regard to the acute and earlier stage of the disease.

In the early stage of valvular inflammation, as I have already said, we sometimes find little rounded prominences like granulations; and at the more advanced period which we are now considering, excrescences present themselves, to which it is most probable that those granular deposits have given rise. They consist of formations more resembling venereal warts than anything to which they can easily be compared; and hence, probably, it was that Corvisart attributed to them a syphilitic origin. They are met with both on the arterial and auriculo-ventricular valves; but, I think, more frequently on the latter, and may be situated either on the surface or edge of the valve: they are generally pretty firm, roundish, or elongated, and sometimes attain the length of several lines, floating loose in the stream of blood.

Occasionally, the thickening of the valves, which seems to depend on lymph effused between their layers or upon the surface, becoming organized, proceeds to a greater extent than we have hitherto supposed, and passes into cartilaginous or even bony induration. By these changes

the natural elasticity of the valves is partially or wholly destroyed, and their functions impaired to a corresponding extent: sometimes they are obviously incapacitated from acting, and remain as rigid projections at the orifices they were designed to close, impeding the flow of blood through them to greater or less extent. In rare, but well-ascertained instances, they become brittle, and are more or less lacerated, folded back into unnatural positions, or presenting loose flaps, moveable by the current, but no longer useful as flood gates. In the aortic valves more especially, the portion towards the free edge is attenuated, or even perforated, and almost eribri-form. It is by no means proved, however, that the changes above mentioned are the results of rheumatism affecting the heart.

In the preceding description of the effects of rheumatism on the heart, I have spoken at large of *pericarditis* and *endocarditis*, but I have hitherto said nothing of *carditis* itself; and for this reason, that I have never seen any satisfactory instance of the muscular fibres of the heart being inflamed, in connexion with rheumatism. I have, indeed, seen the substance of the heart softer than natural when the membranes had been inflamed; but I have never seen any thing which could be called tumefaction, or interstitial effusion, or the formation of purulent matter in the heart after rheumatic fever, though I have seen some of these effects result from its inflammation unconnected with rheumatism.

The changes which the muscular parietes of the heart undergo, in connexion with rheumatism, seem to depend chiefly, if not exclusively, upon mechanical causes. In the great majority of cases in which the valves are diseased, the walls of the heart will also be found changed, and such change generally consists in augmentation of bulk. The most common deviation from the natural condition, in this respect, is an enlargement of the left side of the heart; but there is a remarkable difference in the statements made even by the best authorities, as to whether this increased size of the cavities is more frequently attended with augmented or diminished thickness of these parietes; in proof of which, it is sufficient to mention, that Baillie says it is most common to find them attenuated, and Laennec, on the contrary, that it is most common to find them hypertrophied. In rheumatism, I have no hesitation in stating hypertrophy with dilatation to be by much the most common change.

The most simple explanation of the changes alluded to in the muscular structure of the heart, and the one most generally admitted, is that which connects them with the state of the valves. Now

the most common condition of these parts, as a consequence of rheumatism, is a certain degree of thickening and stiffness, both in the aortic and mitral valves, especially the latter—a degree of thickening sufficient to present an impediment, but not an insurmountable obstacle, to the passage of the blood through the ostia of the heart. This state of matters requires more vigorous action, both from the ventricle and auricle, but of course more particularly from the former; and under this increased action the muscular fibres grow, apparently on the same principle as any other muscle is augmented by exercise. But if the obstacle be greater, such as the heart cannot easily, or perhaps cannot at all, sufficiently overcome, then it is not difficult to understand how the cavities, never wholly emptied, should yield to the slow operation of this continued dilating force, and at length become permanently enlarged, and their exhausted parietes attenuated. I beg, however, not to be understood as holding that these are the only causes of hypertrophy, on the one hand, or of dilatation, on the other.

Where any impediment to the flow of the blood is presented by the valvular apparatus, it is to be expected that the muscular fibres which have to overcome such impediment will be those to be enlarged; and, as a general rule, obstruction at the aortic orifice gives us hypertrophy, with dilatation of the left ventricle; while any obstruction at the mitral valve affects the auricle in a corresponding manner. But there is yet a different state of matters: we may have the aortic valves perfectly healthy, and yet the left ventricle appear unusually muscular. I think it probable that in such cases the muscularity will be found to consist almost entirely of increased bulk of the *columnæ carneæ*, and that the mitral valve will be found thickened, or otherwise changed, in such manner as to have required more than usual effort to make it act. Such, at least, has been the case in several instances of this nature which I have examined; and in one which occurred at St. George's Hospital during the present season, these phenomena were conspicuously displayed. The aortic valves were healthy; the mitral much indurated. The *musculi pectinati* of the left auricle were hypertrophied, owing, I presume, to the obstacle they had to overcome in forcing the blood through the auriculo-ventricular orifice. The *columnæ carneæ* of the left ventricle, too, were very large and strong, having to act upon a stiff and unyielding valve; but the general body of the ventricle (that portion the action of whose muscular fibres had to propel the blood through the healthy aperture of the aorta) was in no degree increased in

thickness, and, in fact, presented a remarkable contrast to the muscular bundles connected with the diseased valve.

In the above cases, where the heart has been permanently damaged by rheumatic inflammation, the diagnosis, to such an extent as serves all the purposes of useful practice, is made without difficulty.

The most conspicuous symptom, supposing the nervous energy of the patient to be unimpaired, is to be found in the action of the heart. This is more turbulent than natural; the contraction of the ventricles occupies a perceptibly increased period, is accompanied by a kind of *heaving*, and there is frequently a greater than natural projection of the parietes of the chest at each pulsation, which is very characteristic. If one end of the stethoscope be applied over the heart, and the fingers applied to the other extremity, the blow may not only be felt but seen, by the impetus communicated to the instrument. There is also a peculiar prolonged swell in the arterial pulsations. If there be great enlargement with thickening, then, in addition to the above sign, there is also dullness on percussion over a preternatural extent of surface, corresponding to the increased size of the viscus. If there be dilatation without hypertrophy, then the dullness exists over an increased space, but without the augmented impulse; and these very simple diagnostic marks are sufficiently clear to afford the means of forming an opinion which will be correct in the great majority of cases. It is remarkable how frequently patients labouring under hypertrophy and dilatation, with the increased force and duration of the heart's action to which they give rise, are yet unaware of any thing unusual. I have repeatedly questioned such persons, and have often found that, unless under excitement, they felt nothing unusual about the heart; and, as a general rule, they do not complain nearly so much as those labouring under merely nervous palpitations without any organic change.

Another almost constant attendant of an old rheumatic heart, is the *blowing sound*; and as this generally bears a relation to the extent of valvular disease and to the force of the heart's action, it is reasonable to conclude that it depends upon the passage of the blood through the ostia of that viscus, whether in the proper course of the fluid, or by regurgitation. But it is to be kept in mind, that it may also arise from causes apparently independent of any permanent disease, and not yet, I suspect, clearly made out, notwithstanding the ingenious and interesting researches of Dr. Williams, which, however, have greatly contributed to the elucidation of this subject.

This sound varies very much in its

intensity and tone, passing by insensible gradations from a soft blowing to a harsh whizzing or rasping sound, and in some—not very rare instances—even striking a distinct musical note, like that from one of the large strings of a harp. That these depend upon differences in the shapes of the apertures or tension of the parts through which the blood passes, is very probable. I have no hesitation in admitting that the intensity of the sounds bears a relation to the extent of valvular disease and force of the heart's action, as a general rule, but I must add, that every now and then we meet with cases in which we find little apparent disease, where there had been much of this anomalous sound, and *vice versa*—clearly proving to those who have no theory to support, that there is something more in the phenomena than is yet “dreamt of in your philosophy.”

ON HYDROPHOBIA.

To the Editor of the Medical Gazette.

SIR,
I SHALL make no apology for sending you an account, somewhat minutely detailed, of a case of hydrophobia which occurred a short time ago at the Middlesex Hospital, because such a fearful interest is attached to this disorder that there is scarcely any circumstance connected with it the relation of which can appear superfluous. Indeed, the whole nervous system becomes affected by it in such an extraordinary and inexplicable manner, that its moral as well as its physical symptoms, and the state of the mind as well as that of the body under it, are inquired into by most persons with almost equal interest.

I am further induced to offer the following case for insertion in your journal, because although in a practical point of view it may be thought to be less interesting than some others, yet in one respect it appears to me to be instructive and likely to be useful.

To those who have witnessed several cases of hydrophobia, or who have paid much attention to the subject, it is well known that many of the symptoms which attend it may vary greatly in different instances. But it ought to be known, more generally than it is, that the peculiar and essential symptoms of the disorder may in some cases be very slightly developed, so as even to be overlooked through the greater prominence of other symptoms which are bet-

ter known as characteristic of a different pathological state.

It may be useful, therefore, to publish a case like the following, which shows that in its general aspect hydrophobia may closely resemble phrenitis or extreme cerebral irritation, and yet may run its usual course, and terminate as quickly and in the same manner, as when its distinctive symptoms have been far more strikingly displayed.

Your obedient servant,

FRANCIS HAWKINS, M.D.

Physician to the Middlesex Hospital.

Curzon Street, May Fair,
October 19th, 1837.

William Hayes, aged 28, a tailor, applied for admission into the Middlesex Hospital, on Thursday morning, October 5th, 1837, complaining that he was unable to drink; that the noise of water appeared to choke him, and to stop his breathing; and that the same effect was produced by a current of air, if the hand were passed quickly before his face, his eyes being shut. He was evidently in an anxious and excited state. Pulse about 80, quick and slightly irregular. Tongue white, and covered with a creamy fur. His bowels had been open twice this morning.

The account which he gave of himself was, that about two months since he had seen a dog pelted by some boys in a canal, and the animal, whilst he was endeavouring to help him out of the water, had fastened upon his hand and wounded three of his fingers: the nail of one was torn across, and had afterwards come off. After he had beaten the dog, as an ungrateful cur, the boys drove him away, and of his subsequent fate he had no knowledge. He persuaded himself that the dog could not be mad because he was in the water and barked at him in a natural way, and he had adopted therefore no measures of precaution. The wounds on his hand had healed readily enough, the scars being still visible on two of his fingers. He positively denied having been anxious about the bite; yet his remarks indicated rather more than a common acquaintance with the ordinary symptoms of hydrophobia. He declared that he had been temperate, and that his health had been good; but he added that he had always been nervous, which he explained by saying that he had been subject to tremors. He went on to say that he had suffered no inconvenience from his accident until two days since,

when pain occurred in the hand which was bitten: he described it as a stinging pain, extending up the arm: indeed, there was uneasiness, he said, in the whole of the right side. On the night before his admission he had gone to bed feverish, and thought he had taken cold, his throat being slightly sore. He was unable to sleep, and got up to drink, but water appeared to choke him. He went out for medicine, and finding no shop open, applied at the hospital, where some pills were given to him, which he took and returned home to bed, but was still sleepless, and he had been able to take little or no breakfast; whereupon he came again to the hospital and requested to be admitted.

His own history of his case was confirmed on the following day by his father, to whom he had written from the hospital nearly in the following terms:—"I am afraid I have got the disorder which I told you of on Sunday,—the dog,—I am now at the Middlesex Hospital," &c.

It appeared also from the account of one of his fellow-workmen, that on the Monday before his admission he first complained of an uneasy sensation in his hand, and on the Wednesday he was so restless that he declared he could settle to no employment, and was constantly speaking of his hand. On the same night he was feverish, as already related, and was received into the hospital on the following morning. His condition on that day (Thursday, October 5th, 12½ p.m.) has already been described. He was more like a person under the dread and expectation of evil, and who was striving to make up his mind to meet it, than like one under actual suffering. There were no involuntary spasms apparent at first sight, and yet, on close observation, a slight catch in his breathing,—as if an inspiration were suddenly arrested, and followed by a short pause,—might occasionally be detected. His conversation and answers, although rapid, were clear and collected. But the tone of his spirits was very unequal. At one moment he appeared to have convinced himself that his fears were groundless, and endeavoured to laugh them off; at another he gave way to despondency, and anticipated speedy death. He entreated that he might have no experiments tried upon him, unless it were to give him poison, fearing, he said, that for the sake of science his feelings would be but

little regarded. At a subsequent period, when urged to allow his hair to be taken off, he refused with a forced gaiety, alleging as a reason that he should not like to look ill in his coffin. As he refused at this time to attempt to swallow liquids none were offered to him; but, at his own request, some rice pudding was brought, of which he swallowed a small quantity, although with difficulty, and he complained that it was too dry. When moistened with milk it seemed to be more palatable to him, yet after taking a few spoonfuls he soon gave it up again, although he could willingly, he said, have eaten more. He requested that he might not be placed in a separate ward, as the company of the other patients was agreeable to him, and he earnestly begged for some entertaining books of light reading to amuse himself with, without too much taxing his attention. I was desirous if possible to have the cicatrix of the wound extirpated, a measure which might still be advisable if hydrophobia were really threatened; or if the complaint were imaginary, which might contribute to allay his fears and compose his mind. But this measure appeared, on consultation with my colleagues, to be wholly impracticable, because three fingers had been wounded, and one of them probably over the whole of its summit, the nail having been torn across. And at this time certainly the symptoms did not appear to justify amputation of a hand, and that the right hand; for what symptoms were there which might not be explained on the supposition of a state of excitement and irritation, produced, or at all events increased, by the fear of hydrophobia? His present condition being hysterical rather than feverish, some pills were ordered for him containing sulphate of iron in combination with the Pil. Sap. c. Opio and Extr. Coloc. Comp.

At 5 P.M. he complained that he was worse. He was flushed in the face and agitated, the pulse being also somewhat quicker than before: he had taken two of his pills, and passed another evacuation, which was of good colour, but small and worm-like, as if the bowel had been contracted. He professed the same horror of liquids, and declared that he had as much difficulty in swallowing as before. Yet still the motion of water did not appear to excite any actual spasm; he merely remonstrated with those who

once or twice splashed it about, on the cruelty of doing that which was painful to him for their own amusement. Having been asked to suffer his forehead to be moistened, he declared that he would do it himself: accordingly he dropped his hand into a basin placed rather behind him, (because he should do it, he thought, more easily if he did not see the water) and drew his hand hastily across his forehead. Still there was no visible spasm, and he seemed pleased, and boasted of what he had just done. He also swallowed a few grapes, though not with much ease or dispatch; it was observed, however, that he took them faster and more easily when not aware that he was watched.

He was ordered to be kept quiet, and to take ten grains of calomel and two of opium immediately, and that this should be followed up by half a drachm of musk, alternately with a grain of acetate of morphia every second hour.

At 10 P.M. he was cooler and less feverish; pulse quieter and less frequent. He said, with some degree of exultation, that he had slept a little at intervals. He had taken his pills and swallowed his musk with tolerable ease. He thought he should like to have some grapes placed by him, but was better pleased that these, and whatever else was brought to him, should be covered up at first, than that they should be at once exhibited to him.

In this state he was left, endeavouring to compose himself to sleep, and he continued quiet until nearly 12 o'clock, when he was unfortunately disturbed by the entrance of some of the medical officers into the ward. He resented this disturbance with great irritation, and became quite furious when asked if he would drink some water. He began to rave and became ungovernable, and from that time in fact until the moment of his death, was constantly in a state of frantic delirium. Early in the morning, upon seeing in the ward one of those gentlemen who had disturbed him at night, he darted up, and leaped over one bed after another with surprising strength, and it was with difficulty that he was at length secured and kept in any degree of order. He could only be persuaded to enter another ward by the assurance that he should walk into it himself, without constraint; or any force being offered to him. He began now to be excessively irritated if any one spoke to him,

or indeed if a single word was spoken in his presence; commanding silence in the most impassioned manner. He appeared to be less offended if he was approached firmly and openly, than if any one advanced towards him softly and cautiously, by which his suspicions were manifestly awakened. In the separate ward he begged to be attended by one of the patients for whom he had conceived a liking, and there was but one of the nurses by whom he could bear to be approached, the presence of any of the rest appearing to irritate him beyond measure; and he declared that no one but those just mentioned should enter the room, or, if they did, he could not be answerable for any violence which he might commit.

Friday, Oct. 6th.—At 12 P.M. I found him greatly altered since the former evening. He had just left his bed, and, on my entrance, he sprang to the middle of the room, where he stood, shrunk and ghastly; his lips and countenance had become somewhat livid, and, in the midst of his ravings, a catch in his breathing might be observed more frequently than before. He suffered himself, however, to be persuaded to lie down again, and promised to allow me to feel his pulse, if I would stand on one side rather than the other. He complained that if he attempted to swallow, his water passed from him involuntarily, a circumstance which has been noticed in this disorder before. He endeavoured with all his might to impose silence on all around him; whoever spoke appeared to speak daggers to him; and he declared that if many persons were to enter the room, and to stare upon him, he could not command himself, but thought he should leap over the banisters. At one moment, having been accidentally left alone, he contrived to lock himself into his room; and it now became necessary to break open the door, and to put a strait waistcoat upon him. When this had been done, instead of struggling with greater violence, he became more composed, and was less irritated by the presence of numerous persons, and by their conversation. He made at that time an earnest request that one of the students (whom he singled out and requested to come forward, because his countenance, he said, was amiable and engaging), might be allowed to attend him. His complexion, since he had been excited by the en-

trance of many visitors, and by his struggles to escape from them, had acquired a better hue, and his breathing was carried on with less interruption, so that he was thought by many, who now beheld him for the first time, to be labouring under a fit of insanity, or the commencement of phrenitis.

As he was still at liberty to get out of bed, it appeared right to confine his feet; but he no sooner caught sight of the leather brought for this purpose, than he sprang out of bed with extreme violence, and it was necessary to bring him back again by main force. During his recent struggles he vomited a small quantity of yellow matter, and wished he could be sick again. I directed, therefore, two grains of the potassio-tartrate of antimony to be given to him, on some bread sopped in milk, which he had asked for. It was doubtful whether he swallowed it; but soon after he allowed me to put two grains more upon his tongue, which presently excited vomiting, and he expressed himself as being greatly relieved. This remedy had the effect of reducing the force and frequency of the pulse; and it was directed that a similar dose should be given to him in an hour's time; after which a grain of calomel, with a grain of muriate of morphia, were to be given every hour.

Between five and six in the afternoon his state was considerably changed. He had become more and more delirious, yet his memory, perception, and reason, appeared at times to be perfectly correct. His temper, however, had become much exasperated, and he expressed his wrath by sometimes spitting violently about him. He had vomited two or three times, and was besides constantly pouring out a large quantity of saliva. The force of the temporal arteries was greatly reduced. Attempts had been made to administer the morphine, but without much success. About 11 o'clock, his bed having become very wet with the excessive flow of saliva, it was thought proper to shift him into another, for which purpose, as soon as his feet had been unloosed, he gathered them up, and sat up in bed; a slight retching then came on, upon which he fell back, and almost instantly expired, appearing to sink exhausted, and not as if suffocated by any sudden or permanent spasm.

Examination.—On the following day,

at 2, P.M., the body was examined. It was, at first sight, evident that the blood had remained in a fluid state, for although 15 hours only had elapsed since the time of death, the back had become extremely livid from the subsidence of the blood. The spinal column was opened, and the theca vertebralis having been accidentally wounded over the cervical vertebrae, some clear fluid oozed out, though not more, probably, than the natural quantity. The whole of the spinal marrow was exposed, but no appearance of disease whatever could be discovered in it. Neither was there anything remarkable in the appearance of the brain and its membranes, except a slight partial thickening of the arachnoid, and a very little fluid effused underneath it. In the ventricles there was but a small quantity of fluid, and the choroid plexus was in a natural state. The only remarkable circumstance observed in any part of the nervous structures was a slight but decided vascularity of the pons varolii and medulla oblongata; the surface of these parts was injected with bright red vessels; whereas in no other part of the brain and its membranes had there been any thing like arterial injection observed. When the head was raised at this period of the examination, the fluidity of the blood was rendered further manifest by the appearance of the face, which had become perfectly purple from having been suspended during only a short time over the table.

The membrane lining the fauces and covering root of the tongue was rendered unusually rough and irregular by an enlarged state of the mucous glands.

The mucous membrane of the œsophagus was in some parts abraded, and in other parts its superficial interior lining had the appearance of a fine false membrane. In the stomach the mucous coat appeared to be softened, but there was no breach of its continuity. In some parts and patches of it there was the common appearance of vessels greatly congested. The small intestines, throughout their whole extent, appeared to be perfectly healthy.

The epiglottis, and other parts about the glottis, were dark and highly injected. The lining membrane of the larynx and trachea was also slightly congested; and the lungs contained a good deal of serum. There was a

moderate quantity of fluid in the pericardium. The subclavian veins were empty. In the cavities of the heart there were some dark clots of blood, coagulated, but not firmly.

The principal cicatrix, which was on the middle finger of the right hand, was also carefully examined, but there was no vascularity round it, nor anything whatsoever unusual in its appearance.

REMARKS. — "Can this be hydrophobia?" was the question of numbers, on beholding the poor patient whose case has now been related, even until a very short time before his death. For, in truth, up to a late period of the disorder, there were no decided symptoms manifested which might not be accounted for by an hysterical state of the system in the first instance, and afterwards by a state of delirium, the effect of extreme cerebral irritation, or of commencing inflammation. On the day of the patient's death, when all doubts respecting the nature of his case were in the opinion of some persons removed, yet others, who then saw him for the first time, were positive in their judgment that his disorder could not be hydrophobia; and these were persons not only of general experience, but who had seen hydrophobia before. Nay, it actually happened that some of those who at the commencement of the case were most inclined to suspect it to be one of hydrophobia, were dissuaded from this belief by its further progress, and became strongly of an opposite opinion. However, the manner of the patient's death served to convince some of the most sceptical as to the real cause of it, because it occurred so speedily, and the scene was closed without the typhoid or comatose symptoms which they expected to supervene. The examination, finally, may be said to have proved, both negatively and positively, that the death was truly caused by hydrophobia; negatively, from the absence of every sign of cerebral inflammation or congestion; and positively, from those very alterations of structure, however slight, which are usually found in cases of hydrophobia, and in dogs affected with rabies. Not but that there were some persons to whom all these proofs appeared insufficient, and who professed themselves to be still undecided as to the nature of the case.

For my own part the doubts which I

entertained when first called to take charge of the case were gradually but progressively removed, and became less and less every time I visited him.

Early on the morning of Thursday my opinion was perfectly formed. For I observed that although maniacal symptoms had supervened, yet that when the patient was in his least excited state, the essential symptoms of hydrophobia, viz., the extreme sensitiveness of the cutaneous nerves, and the spasmodic affection of the muscles of respiration and deglutition, were manifested, though still slightly, yet more clearly than before. Nevertheless, while the case was so generally considered doubtful, I deemed it best that it should be treated in a such a manner as seemed likely to afford the patient the best chance of recovery, if his case should *not* be hydrophobia. But late on the Wednesday night so little doubt appeared to me to remain, that I was desirous of endeavouring on the following morning to diminish the sensitiveness of the cutaneous nerves by anointing the patient freely with an ointment containing delphine, while at the same time acetate of morphia or some other sedative should be applied to a blistered surface over the cervical vertebrae. But the frenzy in which I found him rendered this and most other remedial measures almost if not entirely impracticable.

The course of the disorder, whilst it was under our observation, appeared to be divided naturally into three distinct stages. In the first of these the symptoms of hydrophobia were already manifested, although in the mildest manner; then came the stage of maniacal excitement; and lastly that of the exhaustion which immediately preceded death. But previous to these, there was the state of restlessness which intervened between the recurrence of pain in the wound, and the first difficulty of deglutition. And prior also to that was the longer interval between the infliction of the wound, and the secondary pain in the cicatrix. This interval is sometimes termed the period of incubation. Thus we have five stages of the disorder which, I suppose, are more or less distinctly marked in the course of every case of hydrophobia.

On contemplating the foregoing case it is consolatory to find that neither excision nor cauterization of the bitten part had ever been resorted to. For it would

tend to lessen our common security against the worst sufferings of humanity, if those measures of precaution had been adopted early and yet had proved ineffectual.

The period of incubation in this case did not exceed in its duration the usual average; which is also satisfactory, because it would increase the anxiety of those who have the misfortune of living under the apprehension of the disorder, if this period should be often greatly prolonged. There are, however, good reasons for believing that during this period of incubation the poison which has been received may still be thrown off, without producing its effects upon the system. This is credible, not merely because so many escape who have been bitten by rabid animals, but further because the period of incubation appears to be somewhat more uncertain for this than for most other poisons; and because before its effects upon the system are manifested, it has appeared in many cases that the health of the recipient has been impaired by some cause or other, but for which it is possible that his constitution might have resisted its influence altogether. Of those, again, who have been the subjects of hydrophobia, many appear to have been of a nervous temperament, as was the case in the present instance; and if it be true that one constitution is more susceptible of this disorder than another, so may, possibly, the same constitution be at different times.

As soon as the second period of the disorder has commenced, which may generally be known by the recurrence of pain in the wound, extirpation of the cicatrix seems still to be desirable; for although there have been cases in which even amputation has been practised early after the commencement of hydrophobia, without appearing to delay its fatal course even for an instant, yet who shall determine the precise point at which the system has become so much affected as to render this measure useless?

It would seem that the extension of the influence of the poison from the inoculated part to the system at large—that process which appears to take place at the end of the period of incubation—is not necessarily an instantaneous nor even a rapid one; for in this case the pain in the hand continued for several days before the constitutional symptoms

appeared. The cicatrix, however, on a careful examination, presented no appearance of having undergone any recent alteration.

In the third stage of the disorder, when the system has become affected, and the symptoms of hydrophobia are unequivocally manifested, there is no remedy, however severe or violent, of which it would not be fair to make trial, provided that it offered the smallest probability of subduing the disease. The peculiarity, however, of the present case was, that the symptoms were by so many thought to be equivocal, even to the last, that extreme measures were unjustifiable until they had become impracticable, or at least utterly hopeless. In such a case, as long as there was a doubt, who would not have given the patient the present benefit of it?

The frantic state, the high degree of delirium; to which the patient was unfortunately excited, might naturally appear to have accelerated the approach of the ultimate stage of exhaustion; yet I believe that cases of hydrophobia have run their fatal course as rapidly as this, in which there has been far less excitement, and only a little degree of delirium. Again, it may be thought that the remedy which succeeded in this case in reducing the excited state, viz. the potassio-tartrate of antimony, may also have had some share in producing the subsequent state of collapse. However that may be, yet certainly for a time, even by the patient's own statement, this remedy was productive of considerable relief.

The difficulty experienced in this and in other cases of hydrophobia, of administering medicines, and, indeed, of making use of remedies of any kind, drives us to the conclusion that if this disorder, when it has once declared itself, is ever to be combated with effect, it must be by means of injections into the veins. And although the chief manifestations of the disorder are confined apparently to the functions of the nervous system, yet, after all, the cause of them may reside in the blood. This opinion, which I believe is entertained by many persons, is rendered the more probable, if it be true, as we are informed, that rabies may be produced in animals by inoculating them with the saliva of a patient labouring under hydrophobia.

UTERINE DISEASES.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of sending you the three following cases of uterine affection, which belong to a class of complaints as important, perhaps, as any a medical man is called upon to treat, as they but too frequently render the lives of those afflicted with them completely wretched, by the loss of health, and the mind being worn down by bodily pain and uneasiness, and by the apprehension of an incurable disease being established. Should you deem them worth a place in your GAZETTE, they are quite at your service.

The first case occurred when I was clinical clerk under the late Dr. Cholmeley, at Guy's Hospital. The history was as follows:—Mrs. S., ætat. 23, married four years; has had no children; of sallow complexion; suffered before marriage much pain at back part of the head and lower part of abdomen, with great debility. After marriage was much worse, and there was a tumor at the upper part of vagina. Consulted a physician without benefit. The catamenia irregular, and of a green colour, and caused great suffering; micturition difficult and painful; the abdomen tender on pressure; skin cool; tongue coated with a white fur; bowels generally confined. Dr. Ashwell was requested to make an examination; and he reported that the cervix uteri was indurated and inflamed, the slightest touch giving great pain. On her entry a dose of calomel and castor oil were given, to clear out the bowels; after which, Dr. C. ordered the following:—

Pil. Hyd. gr. iv.; Pulv. Ipecac. gr. i.;
Ext. Hyoscy. gr. iv. om. noct. M.;
et Ammon. Sub. gr. v.; Mist. Camph.
3x. bis die. M.

This medicine acted like a charm, and in three weeks she left the hospital quite well.

The next case is a Mrs. F., who two years since consulted me for what she feared was an incurable disease of the womb, as she had been under several medical men, who had done her no good. Her symptoms were very similar

to the first, viz. a bearing-down sensation in the vagina, tenderness of abdomen, the unhealthy look of countenance, and a coated tongue. In this case there was pain in the left side, about the situation of the ovarium, and her illness had come on since her last confinement, when she suffered much from the placenta adhering, and which she said was *torn away*. I gave her the same medicine as was given in the former case, and with the happiest effects. She was cured in one month, and has been well ever since.

The third case is a Mrs. G., æt. 23, whom I attended with her first child two months since. Her labour was natural, but the child lived only twelve hours. I was requested to see her three weeks afterwards, and found her labouring under great pain and tenderness in the hypogastric region, and such a bearing-down feeling in the vagina, that she could scarcely sit. Her pulse quick and irritable, her eye sunken, and her countenance totally altered since I last saw her. As this case was of a more acute character, she was confined to her bed. I ordered six leeches to the pubes, and hot fomentations, in addition to the blue pill and extract of henbane. In one fortnight she was quite well.

This treatment, sir, so efficacious and so easy of practice, is highly deserving of a trial, as such cases but too often resist the ordinary means made use of, and it is to be feared have baffled many men, and reflected not a little discredit upon them in the end, especially after a great deal of local treatment, such as warm injections, ointments, cupping on the loins, and sometimes mechanical supports,—a practice by no means uncommon at the present day.

There is another disease over which the same remedies exert a wonderful influence, and that is hysteria. I have a patient now, who has been completely out of health for months, and has suffered dreadfully from hysterical fits, and who appeared to all her friends to be sinking. I at the first gave her the ordinary remedies—steel, bark, ammonia, and henbane—with but little effect. At last I was induced to give her blue pill, and extract of henbane; and she has not had a fit since the second dose, and is now almost well. I have been surprised that this remedy is so well borne by such delicate females, for

weeks together (for they are generally delicate women), who, if they were to take it but for a few days when in health, would probably be completely salivated.

Hoping I have not trespassed too long upon you, I am, sir,

Your obedient servant,
EDWIN ELLIS.

CHOLERA INSURANCE SOCIETIES.

To the Editor of the Medical Gazette.

SIR,

WHEN the cholera was in the country, in 1832, I called my neighbours together and explained to them the best preventive measures that could be adopted, and the propriety of assisting each other in a time of such a general calamity.

We succeeded in procuring seventy-five families to pay from 6d. to 2s. 6d. per week, and in four months we had in hand fifty pounds. It was remarkable that, in the adjoining villages and neighbourhood, there were seven cases, and only one in town; but *not one case existed after the formation of our Society*, which I attribute to the moral confidence they all felt—the *parent of a physical energy sufficient to resist the contagion*.

The money was returned to the assurers when the cholera left the country, with interest, as it had been deposited in a Savings' Bank.

I have sent you a copy of our rules, that if any of your readers may choose to recommend such a system at the present time, they may see them. They will, I beg to observe, be entirely unsuccessful in any appeal they wish to make to the working people, if they allow the servants of selfishness to exercise, use, or govern in any degree, a work of good will. The guardians are useful as an amputating knife in cutting off the corrupt parts of the body politic, but there is as much healing virtue in the one as the other, and they mar, ruin, or neutralize, every attempt to improve the character and conduct of the working people. They have

done as much mischief in arresting the progress of good will amongst the people, as they have of profit to the absentees and usurers, for whose particular benefit they were created.

I remain, sir,
Your humble servant,
H. L. SMITH.

Southam, Warwickshire,

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

A Lecture on the Functions of the Lymphatic System. By ROBERT JAMES GRAVES, M.D. M.R.I.A., &c. Second Edition.

THIS lecture, which was originally published in 1827, and again in 1834, did not fall under our observation till very recently; a circumstance which we regret, as it contains some very interesting original opinions, not only on the subject of which it specifically treats, but on various others incidentally alluded to.

We find, for example, that the view taken of the functions of the lymphatic system, by Dr. Graves, ten or twelve years ago, is precisely analogous to that put forward by Müller, in his valuable work on *Physiology*, the translation of which has just appeared. Dr. Graves observes,

“This great and marked distinction may therefore be made between vertebrated and invertebrated animals, that the vascular system of the former includes two parts, one containing red blood, circulating in arteries and veins, and the other a transparent colourless fluid, conveyed towards the heart by the lymphatics; while the vascular system of the latter is single, being confined to vessels circulating a colourless fluid.

“The solids of red-blooded, compared with those of white-blooded animals, present a difference corresponding to that of the fluids: for as the vascular system of the superior classes contains both red and colourless fluids, so we find both red and white structures or tissues in the solid portions of their bodies. In the mammalia, the muscles both of voluntary and involuntary motion, which constitute so great a part of the bulk of the body, belong to the red structures; among the white may be

enumerated the cellular, serous, synovial, and fibrous membranes, ligaments, cartilages, the animal basis of bone, &c. In the invertebrated animals, on the contrary, the whole solid system belongs to the class of colourless tissues, or at least includes nothing similar to the red solids of vertebrated animals.”

And again:—

“The following reasons seem to me conclusive in proving, not only that the white tissues have a proper circulation of white blood, but also that they are capable of undergoing a two-fold species of inflammation:—

“1st. When we irritate the white part, it soon becomes red, from the appearance of minute vessels carrying red blood. These vessels appear often so suddenly, that we are forced to admit their previous existence in the part; and the existence of vessels being thus proved, it follows that the fluid circulating in them must have been white, for otherwise they would have been visible. This simple experiment on the living animal enables us to prove the existence of minute vessels in white parts, conveying in health a white fluid, and directly continuous with the arteries, as is shown by the immediate entrance of arterial blood into these vessels, when the part is stimulated*.

2d. We find that the pseudo-membranes so often formed between the pleura pulmonalis and pleura costalis, are capable of becoming vascular, red, and inflamed, and are sometimes found covered with an exudation of coagulable lymph.

“It is quite evident that in such membranes, quite unconnected as they are with any red part, the vascularity observed during inflammation must belong to themselves. When the inflammation subsides, the vessels into which red blood had found its way again convey a white fluid, and consequently become invisible.

“3d. Where a serous membrane covers another white structure, in the manner that the synovial membranes are attached to the cartilages and capsular ligaments of joints—when we find, as is often the case, that the internal surface of the joint becomes highly red and inflamed—we must attribute this morbid vascularity to one or other of

* See experiments by Hunter, in his *Treatise on Inflammation*. Also Thompson on *Inflammation*.

the white structures, for in this case no other structure enters into the composition of the part.

"4th. The synovial membranes furnish us also with conclusive evidence against the opinion that the *serous exhalation* is not derived from, but is merely an exudation through the serous membrane, and that this exhalation is derived from some part furnished with red vessels, for the synovial membranes in health are covered by a copious exhalation, serving to lubricate the articular cavities; and which secretion cannot have been produced except by a white structure, as none other enters into the composition of the joint.

"5th. The exhalation of cellular and serous membranes is closely allied, in chemical composition, to the serum of the blood, and is therefore probably derived directly from it, as it circulates in the white parts, and not indirectly from red blood circulating in red parts.

"6th. That a circulation is carried on in the white parts, has been proved by the experiments of Mayer, who detected prussiate of potash in the tendons, ligaments, &c. in a few hours after he had injected a solution of this salt into the lungs of animals.

"All these reasons seem conclusive in proving that the white tissues are during health provided with vessels continuous with the arteries, but conveying only the serous portions of the blood; and that in disease these vessels admit red blood, and thus these parts become the seat of red inflammation.

"In the higher order of animals, as the mammalia, all the blood is sent from the heart through the arteries, to be distributed to all parts of the body. This blood consists of two portions—a red fibrinous portion, and a serous albuminous portion. The two portions together circulate through the arteries, and are returned by the veins, passing through parts of a red colour and fibrinous composition; while a part of the serum enters into the minute arterial branches, which, supplying the white parts, do not admit the red or fibrinous portion; and thus a serous or white blood is distributed to the white structures, whose albuminous secretions and albuminous basis agree so exactly with the composition of the fluid thus destined to support their nutrition and carry on their functions.

"As a serous or white blood is con-

veyed from the heart to the white parts, it is evident that some means must be provided for its return towards the heart; and for this purpose we find these parts plentifully supplied with lymphatics, vessels which discharge the office of conveying back the white blood from the white structures, and which may therefore be called the *veins of the white parts*."

If these extracts be compared with pages 275, &c. of Baly's translation of Müller, the similarity of the doctrine, with regard to the lymphatics, will become obvious, and the same remark with respect to Breschet has already been made in the review of his work, in the last number of our "British and Foreign" contemporary.

While we are on the subject of Dr. Graves's claims to originality, which we are desirous to vindicate, we may allude to the fact of Carus having adopted very nearly the same expressions as the physiologist of Dublin. Thus—

"It deserves particular attention," says Carus*, "that we meet in the vertebrated animals a repetition of a vascular system, destined to carry a simple colourless blood (the lymphatic system), to which is added another system of vessels of a still higher rank, and destined for the circulation of red blood: this repetition is precisely analogous to the repetition of the ganglionic system of nerves, in the higher classes of animals, after the cerebro-spinal nerves have been superadded to that system."

While in the lecture before us, published, be it remembered, a year before the work of Carus—

"In the higher classes of animals there are not only two circulating systems, one of red blood and another of white blood, but also a twofold system of nerves, the cerebral and the ganglionic; the latter of which, in invertebrated animals, seems to perform all the nervous functions necessary to their state of existence, while these animals are also remarkable for possessing only a simple vascular system."

To the lecture are appended some "additional notes;" and in these we observe two circumstances worthy of notice. The first is the anticipation of the discovery of lymphatics in the brain,

* Grundsätze der vergleichenden Anatomie und Physiologie, &c. Bänd. iii. p. 2. Dresden.

very distinctly stated in the following passage :—

“ In invertebrated animals, the vessels carrying white blood back to the heart, *i. e.* the lymphatics, are simple, and cannot, *when minute*, be in any way distinguished from the minute ramifications of the veins in higher animals. The similarity of structure between minute vessels containing white blood in a state of health, and minute veins, is well exemplified (as argued in the text) in the conjunctiva, where white veins suddenly become red veins, when inflammation supervenes. In the same way it is extremely probable, that the lymphatics of the brain, answering to the white veins of the lower orders of animals, and the short simple lymphatics observed in other parts of the structure, escape notice only because they empty themselves very speedily into the venous system of red blood.”

The second point of interest to which we refer, as contained in these notes, is the view given of the functions of the placenta :—

“ It is probable, therefore, that the maternal vessels and those of the fœtus may carry on an active interchange of principles, although no direct communication by opening or mouths exists between them. The vessels of the mother may carry principles necessary for the nutrition and respiration of the fœtus, and may freely impart them to its vascular system; while, on the other hand, every thing which requires to be excreted from the fœtal system, may, in a like manner, as easily find its way into the maternal veins, and so be gotten rid of. I cannot help thinking that this view of the placenta, which, by comparing the relation between the ultimate ramifications of the maternal and fœtal vessels with those of the secreting vessels and ducts in glands, points out not merely the analogy, but almost the identity of this relation, deserves the attentive consideration of physiologists. It is to Müller that we are indebted for understanding the analogy which the lungs bear in their structure to glands; and his researches first suggested to me the idea, that the placenta may be considered as a temporary gland, destined for the nutrition and respiration of the fœtus.”

Now in making the above extracts, we do not mean to charge Carus, Müller, or Breschet, with plagiarism; but

when we find views and opinions attracting notice, as coming from the pens of foreigners, which have previously been announced by a distinguished countryman of our own, we feel it to be but fair to state the facts simply as they are, that the credit which always attaches to originality may be bestowed where it is justly due.

An Essay on Pyrexia, or Symptomatic Fever, as illustrative of the nature of Fever in general. By HENRY CLUTTERBUCK, M.D. 8vo. 136 pp. Highley.

So long since as 1804, Dr. Clutterbuck endeavoured to prove that all fevers are symptomatic, and depend on inflammation of some part of the body, and, therefore, that fever *per se* really does not exist; the disease usually known by the name of idiopathic fever being an inflammatory disease, the seat of which is the brain; and though it would appear to occupy the entire organ, yet it does so unequally and differently at different times, and in different individuals.

The present work is devoted to that constitutional disorder termed Pyrexia, or Symptomatic Fever, and which the author believes to be invariably produced by, and, therefore, always dependent on, inflammation. Its characteristic symptoms are, heat of skin, frequency of pulse, thirst, and foulness of tongue. Cullen's definition is objected to by Dr. Clutterbuck, on the ground that the “*viribus artuum imminutis*” of the celebrated Edinburgh professor does not apply to pyrexia, but is peculiarly characteristic of idiopathic fever. In other words, our author regards the prostration of muscular strength, alluded to by Cullen, as being the consequence of inflammation of the brain, and, therefore, as not being observed in inflammation of other organs.

After examining the state of the blood in, and the varieties of, pyrexia, the Doctor examines the causes of this affection. All kinds of irritation, he observes, are not capable of producing it. It seems, indeed, to be that kind which inflammation excites, that is the chief, if not the sole cause of it. It is, indeed, true that a number of other circumstances, not very obviously connected with inflammation, give rise, at times, to febrile action. Mercury and

antimony, for example, produce this affection, and their influence is thus explained: "These substances appear to be taken up by absorption, and, being carried into the bloodvessels, probably act on these, so as to excite them into increased action, if not to produce actual inflammation on their surfaces." This is somewhat analogous to Messrs. Morgan and Addison's view of the operation of poisonous agents generally, on the body. The states of menstruation and pregnancy, which sometimes occasion febrile symptoms, depend on some condition of the uterus very closely allied to, if not identical with, inflammation. Dr. Clutterbuck, however, admits that some exciting causes (as violent exercise, the hot bath, the use of alcohol, &c.) occasion excitement of the vascular system, and raise the temperature of the body, yet without exciting inflammation. "It may be questioned, however, whether the state thus induced is really of the nature of pyrexia; for it is not attended by that general disturbance of functions, and the coated tongue, that are observed in genuine symptomatic fever: they appear rather to be cases of simple vascular excitement, which soon subsides again; with no other result than a degree of weakness or exhaustion, that naturally follows over excitement of any kind."

In speaking of the nature of pyrexia, Dr. Clutterbuck says, "Upon the whole, with regard to the intrinsic nature and mode of production of *pyrexia*, or symptomatic fever, it may, I think, be concluded that *inflammation*, considered as the ordinary remote cause of this affection, acts as a source of irritation to the brain, disturbing its vascular action, and thereby disordering its functions, but differently in the different stages. The change thus taking place in the condition of the brain, influences subsequently, and in a corresponding manner, the whole *sanguiferous system*" by sympathy.

The three last sections of the work are devoted to the consequences and treatment of symptomatic fever.

The foregoing extracts and remarks will put our readers in possession of the principal topics discussed by Dr. Clutterbuck. We have preferred giving an analytical rather than a critical notice of his work, on account of the necessarily limited space we could devote to it.

There are several opinions expressed in this "Essay" which some persons may not be disposed to admit: but being the opinions of a physician of great experience, and of one endowed with a highly cultivated and logical mind, they require examination. Moreover, the works on Symptomatic fever are very small in number compared with those on Idiopathic fever, and hence, therefore, Dr. Clutterbuck's book is the more valuable, and will be perused with so much the more interest, even by those who may not assent to all his opinions. In conclusion, we beg to thank the Doctor for his "Essay," and strongly recommend it to our readers.

—
Die Pest des Orients. Von Dr. C. J. LORINSER. 8vo. pp. 461. Berlin, 1837. Schloss.

THIS is a work of much research. The first part is occupied with an historical account of the plague; the second with its pathology; and the third with the preventive measures adopted in different countries for its counteraction. In an appendix is subjoined a narrative of the last plague which ravaged Silesia between the years 1708—1712.

—
Die Sinnestäuschungen. Von Dr. F. W. HAGEN. 8vo. pp. 348. Leipzig, 1837. London, A. Schloss.

THIS is a curious treatise on illusions of the senses. The author investigates at considerable length their causes and varieties, their relations to bodily and mental diseases, their importance in a medico-legal point of view, and the appropriate methods of cure.

MEDICAL GAZETTE.

CICERO.

THE PROFESSORSHIP OF PATHOLOGY.

It is rumoured that many of the Council of the New London University are still in favour of the establishment of a

pathological chair; and it has even been said that on a division there was a majority of one only against the infliction of this new course of lectures on the wearied and worried students of London. It is strange that the formidable minority of the Council did not reflect that the number of compulsory courses is already so great, that most students find it difficult, not to say impossible, to attend them. It requires undaunted energies, and the most skillful distribution of time, to attend during the same season the lectures required by the College of Surgeons and the Society of Apothecaries, together with the due proportion of dissections and hospital practice; and hence, as we lamented in a former article, this complicated knot of difficulties, hard to unloose, is cut with the greatest facility—the pupil, we fear, too often contenting himself with the certificate, instead of the lectures.

The outcries for additional lectures (perhaps we ought rather to say, for additional certificates), are occasionally heard even from those who are chiefly contemplating a course of study for the general practitioner; but to make a complete physician so much is required by some theorists, that we are reminded of the requisites for a poet, as given by Imlac in *Rasselas*, and feel inclined to answer with the Prince, changing only one word,—“Enough, thou hast convinced me that no man can ever be a *physician*.” Thus Dr. Rothe*, a celebrated German writer, recommended the study of logical, metaphysical, moral, political, statistical, technological, agricultural, mathematical, geographical, chronological, genealogical, heraldic, diplomatic, numismatic, and historical works, to precede chemistry and anatomy;—as a kind of whet to the student’s appetite, we suppose.

We will do the Council the credit to take it for granted, that if they increase the ordinary curriculum of the London pupil, they will increase the time of study in proportion, and not drive more of our alumni to the sham-certificate system. But the misfortune is, that if they merely augment the time in proportion to the augmentation of lectures, they will not do enough; for in London, as elsewhere, the curriculum is over-much for the time. On the Continent five years are a usual period; but then the courses to be attended are so numerous, that it is obvious to every practical man that the graduates must have about as much knowledge of many of the subjects as might be gathered from one of Pinneock’s catechisms. At Edinburgh things are as bad, or worse.

“The period of study for graduation in this University being four years, and the imperative courses being fourteen in number, while the more important ones, such as anatomy, chemistry, surgery, and practice of physic, are always attended at least twice, though the statutes do not require this, from unwillingness on the part of the medical faculty to prevent all recourse to extra-academical instruction, the student is occupied in the class-room at least four or five hours a day on an average, independently of the time required for practical chemistry, practical anatomy, and hospital attendance. Such being the case, it is obvious that any course not really necessary must be injurious: and that any course which jars with another, from the similarity of its subject and station in the order of study, must be still more hurtful”*.

The curriculum of the Worshipful Society in London is even more difficult to put into execution, as twelve courses of lectures, besides dissections and hospital practice, are there crowded into two years and a half; besides which, the student usually attends during the

* Letter to the Lord Provost, &c. by James Syme, Esq., p. 4 and 5.

* Young’s Medical Literature, p. 3. Second edit.

same time (as witness his certificate) the lectures on surgery required by the College.

Suppose, however, that the time were so much extended as commodiously to include not merely the long list of lectures now prescribed, but also one course more; ought that one to be upon pathology? Decidedly not. All those who value the art of medicine as prolonging human life, and subtracting some units from the sum of human misery, will agree with us in preferring a course of lectures on public and private hygiene. We should not then hear it confessed, and complained of on all sides, that some of the simplest problems relating to diet are yet unsolved; nor would Assistant-Commissioner Mott be able to assert, without fear of contradiction, that medical practitioners do not know how much a healthy man should eat. We do not, however, recommend any addition to the already overloaded curriculum. One student in a hundred, with abundance of time at his command, may attend such a course; but for the mass it must be sufficient to treat of some of the more prominent points of private hygiene in the lectures on physiology; while public hygiene, being evidently a point where law and physic touch, will find its place in forensic medicine.

If pathology means, as it ought to do, the doctrine of symptoms, it is already included in the lectures on the practice of physic and the practice of surgery; if it means, as it is often made to do, an account of morbid anatomy, again it forms a large part of the medical and surgical lectures, besides being amply set forth in the dead-house of every hospital. This is by no means the weakest point in our modern medical education; and thousands know the appearances commonly found on dissecting a phthisical or apoplectic patient, who do not know how much bread

should be allowed to the inmates of a union workhouse. It is worthy of remark, that at Edinburgh they have, besides their professor of medicine, a professor of the institutions of medicine; so that the doctrine of symptoms, at any rate, must be plentifully taught. As to the other thing which pathology has been made to signify, morbid anatomy, Dr. Thomson, the professor of pathology, believes that neither the professor of the practice of physic "nor of the Institutions, will affirm that they have hitherto been accustomed to teach their respective departments of medicine with the aid of coloured delineations of diseases, and with a particular reference to the morbid preparations preserved in the Museum or of the Royal College of Surgeons, so as to have anticipated, or in any degree superseded, the purpose, uses, and advantages of the plan adopted by the professor of pathology in teaching pathological anatomy*."

It appears, too, that there are three surgical professors—one of surgery, one of clinical, and one of military surgery; so that it would be strange indeed if the doctrine of symptoms, and the marks which disease leaves in the human frame, were not sufficiently taught. Dr. Thomson, it is true, in the above extract, affirms that morbid preparations and coloured delineations of diseased structure are little attended to by the medical professors. If so, the omission ought to be supplied; an easier thing, assuredly, than saddling the exhausted student with a fifteenth certificate. But we deny *in toto* the justice of this allegation as regards London, in the schools of which, coloured drawings, plates, and preparations, are systematically exhibited by the lecturers on medicine and surgery.

An unpleasant feature of the contro-

* Remarks on the "Memorial of the Town Council of Edinburgh, &c. &c. respecting the Professorship of Medicine and General Pathology," by the present Professor, p. 6.

very raging at Edinburgh on this subject, is, that it has been made to assume a tradesman-like rather than a scientific appearance:—"If we don't sell a very cheap article," cries the shopman to his master, "our second-rate customers will all go over the way." "If we don't make things very easy to students," cry the Edinburgh professors to the Town Council, "they will all go over to Glasgow." But even if you come down to the Glasgow standard, how can you in anywise stand a competition with Aberdeen and St. Andrew's? On the other hand, Dr. Thomson shows that some of the medical students and graduates of the University of Glasgow petitioned the *Senatus Academicus*, on the 14th of December, 1833, to add several courses to those specified in the regulations then lately published—viz. "one course of anatomy, practical anatomy with actual dissection, practical chemistry, diseases of the eye, natural history, and medical jurisprudence*." How many more months or years the petitioners wished also to see added to the time of study, does not appear; but unless a considerable number of months (say fifteen, at least) had been tacked on to the curriculum, we fear that the temporary lustre which a Glasgow diploma might acquire from this splendid array of subjects, would soon have faded away; for that impartial tribunal, the medical public, would not have been slow to discover that an M.D., or newly-certificated man, knew about as much natural history as a young lady fresh from school, or a Russian surgeon†.

* Remarks on the Memorial, &c. p. 17.

† Some ten years ago, it appeared from certain notices in the newspapers, that the Autocrat of all the Russias wished to have a batch of English surgeons. They were to be divided into two classes, the higher one receiving about £60 a year. The first-class men, however, were not to get this handsome salary for nothing; on the contrary, a most appalling catalogue of arts and sciences was required from them. Among other things they were to be skilled in natural history, and be able to write Latin. We never heard whether his Imperial Majesty succeeded in ob-

We, however, have nothing to do with these party squabbles, and would wish to argue the question on higher grounds. It is of no importance to the common weal whether students prefer Glasgow to Edinburgh, or *vice versa*; but it is of the greatest importance that they should attend a reasonable number of judicious lectures, and, therefore, that they should not be overwhelmed by such numerous courses, that professor and pupil are alike seduced into a common conspiracy, while the certificate becomes the assertion of what, in the polite language of the Houyhnhnms, was called—*the thing that is not*.

The lectures being once reduced within sensible limits, we should certainly advocate the adoption of the excellent suggestion of Dr. Kerrison, in our number for August 19, of having some plan for ascertaining the actual number of times each pupil had attended.

In addition to this, we would propose another improvement, of equal importance—perhaps even of still greater, as it might be put into certain execution, without our being obliged to rely on the faithful austerity of the whole army of lecturers.

It would consist in dividing the whole course of study into two or more portions, and obliging the pupil to pass a preliminary examination in certain subjects, before he entered upon the study of others. Thus, supposing the five years' apprenticeship to be still continued, the pupil might pass an examination in botany, chemistry, and reading prescriptions, at the end of half this period, thus leaving the remaining half for the uninterrupted study of the other branches of his medical education.

taining any first-class recruits in this country. If his Majesty's examinations were strict, then unquestionably we have not yet seen the surgeon capable of coming up to his demands; but we conjecture that the Czar was lenient, and would have been satisfied with answers culled from the ninepenny treatises we referred to above.

At present it often happens, as every practical man knows, that all the subjects are left unstudied, and almost untouched, till the last few months, when, by the aid of manuals, grinders, and midnight lucubrations, the idler attempts, and too often succeeds, in attaining the wished-for goal:

—— “post tot discrimina tutus!”

[Since the above was written we have received some documents regarding the Pathological Chair in Edinburgh; they will be found at page 222. We understand that Dr. Thomson, who had come to London for his health, has returned to Edinburgh for the purpose of teaching the class himself, the Town Council having refused to allow his proposed deputy to officiate.]

CHOLERA.

CONSIDERABLE alarm was excited some days ago by the reported re-appearance of cholera at the eastern extremity of the metropolis. The fact is, that well-marked cases of the disease have lately occurred on board the Dreadnought, and in some other situations, but without shewing any decided tendency to assume an epidemic character. Now in this there is nothing beyond what has been witnessed every autumn since the first irruption of the disease in England—the cases, however, having progressively become more rare. Three months ago we saw a well-marked case of cholera at the west end of the town, but it evinced no disposition to spread. Lately, a similar case occurred at St. Bartholomew's Hospital, when the only circumstance which led to any doubt of its being cholera, was, that the patient recovered.

Should the disease become epidemic (of which, however, there is at present no indication), we hope that our professional brethren will give a fair trial to the plan of administering sugar of lead with minute portions of opium, so

strongly recommended by Dr. Graves in a late number of this journal.

DEATH OF DR. MACKINTOSH.

WE regret to have to announce the decease of Dr. Mackintosh, of Edinburgh, which took place last week, in consequence of an attack of typhus fever. Dr. Mackintosh was the author of an elementary work on physic, and of various papers in the medical journals. He devoted a great portion of time and labour to the investigation of cholera, and has made some important contributions to its morbid anatomy, the results of which were communicated to the late scientific meeting at Liverpool. He was a zealous and active man, perhaps a little too *energetic* as a controversialist. He had a considerable class, and his death will be severely felt in the school with which he was connected, leaving, as we believe it does, a blank both in medicine and midwifery.

ST. GEORGE'S HOSPITAL.

Sequel of the Case of Strangulated and Mortified Intestine—Operation for Necrosis of the Tibia—Severe Injury of the Leg; Amputation.

THE case of long-continued strangulation, reported in our last number, was just beginning to offer a chance of recovery, when the account was closed on the 17th, twenty-four hours after the operation. During the rest of the day fluid healthy fæces continued to pass through the wound, and there was no tenderness of the abdomen; but the report at 9 P.M. was, that she had vomited repeatedly, with greater weakness, and a pulse of 130 or 140, and frequent spasmodic attacks of pain, during which the folds and turns of the intestines were seen with the most curious plainness through the parietes; and during the spasms the contractions and consequent alterations of position in the several bowels, were easily perceptible.

Ordered: two eggs, and two gills of pale brandy.

Oct. 18th, 9 A.M.—Slept comfortably; less pain, though still a good deal in spasmodic attacks; tongue loaded and dry; pulse only 100, weak and fluttering; sickness continued at intervals. Fæces constantly passing away, so that the distension of the abdomen is much lessened.

Ordered to continue the eggs and brandy, which she likes.

1 P.M.—Sick occasionally; milk and water, and porter, keep down better than the brandy and egg, which she has brought up.

Ordered a mutton chop also.

9 P.M.—Scarcely any pain now left; but when it does come on it is spasmodic, and the convolutions of the bowels are still very evident. No sickness except once, about an hour after her meat; pulse 120, soft, more full; skin warm and comfortable; tongue rather glazed and dry.

19th, 9 A.M.—Slept a good deal; no pain; no sickness. She is weak, however, and the pulse rapid; skin rather colder, and clammy occasionally.

Red wine, two glasses; tapioca, &c.

9 P.M.—Very comfortable during the day, but this evening the spasmodic pains have returned again at short intervals, during which the spasm of the bowels is very apparent; skin comfortable, however. Feels much better.

20th.—The pains of last night proved to have been connected with the uterus, for early this morning symptoms of miscarriage appeared, since which she has been quite free from pain, and the abdomen is soft and flaccid. She menstruated as lately, however, as ten weeks ago. She seems more exhausted, though quite free from any disturbance connected with the strangulation.

1 P.M.—Weaker; pulse 130; fæces passing readily; discharge from the uterus continues, though not very great. Says she feels much better, though exhausted; not sick once since yesterday afternoon.

21st, 1 P.M.—Very restless during the night; cold clammy skin; pulse not perceptible; looks exhausted. She has just taken a chop, however, besides wine and other things.

6 P.M.—Died,—a little more than five days after the operation.

On examination of the body the next day, there was found to be no trace of inflammation of the peritoneum generally. The part strangulated was the ilium, about six inches from the cæcum, and the two ends of the bowel were adherent to the edges of the femoral ring; and the skin being thin, there was not half an inch distance from the orifice of the mortified bowel to the points of adhesion; so that there seemed every reason to believe that, if she had lived, the artificial anus would have been cured. The part below the opening was small and contracted; that above thickened and vascular, (as would be expected after nine days' strangulation,) but nearly empty, and apparently per-

forming its functions well, without inflammation. So also was the stomach, which was strongly contracted in the middle, and contained only a little brown fluid, though she had taken a chop four hours only before her death, while pulseless and cold, and apparently incapable of digesting food.

The uterus was large and dark coloured, and in the interior the membranes of an ovum were found adherent to the fundus; while the rest of the surface of the uterus, from which the membranes had separated, looked almost sloughy. No embryo, however, was found.

The ovaria were very vascular, as if inflamed, especially the right; both contained numerous Graefian vesicles, and in the right was a large corpus luteum, beautifully developed, from which, doubtless, the ovum had escaped. Around the uterus and ovaria was about a table-spoonful of dark purulent fluid, as if from inflammation of the peritoneal surface of those organs.

The result of the examination, coupled with the preceding symptoms, was evidently such as to justify the conclusion, that she had nearly recovered from the effects of the long strangulation and mortification of the intestine, and that she would probably have got quite well, but for the unfortunate coincidence of a pregnancy, and consequent miscarriage, while in a weak and exhausted condition.

The only operation performed last Thursday, the 20th, was for necrosis of the tibia, by Mr. Hawkins. The patient was a young man, whose leg had been crushed on a railroad six months previously, so as to cause much local mischief and subsequent inflammation, and the death of a large portion of the bone, which had been extensively denuded by the accident. An incision three or four inches long was made to the bone in its upper half, and the shell of new bone removed by three or four applications of the trephine. Out of the opening thus made, several inches of dead bone were extracted. Another incision was then made near the ankle, and some bone having been sawn out by the trephine in the same manner, some more dead bone was extracted, which was too securely wedged in by new bone to be extracted from the upper opening. Seven or eight inches of the shaft were thus dead, and removed. The inflamed parts bled a good deal, and some blue lint (lint dipped in a saturated solution of sulphate of copper), was therefore placed in the cavities of the bone. A good deal of inflammation, and slight sloughing of the skin, followed the operation, accompanied by a good deal of fever, but the wound

became quite clear by the 24th, and has continued healthy since that time till now (Nov. 1st), and the cavities already a good deal filled with healthy granulations.

On Thursday, October 23d, a man was admitted in the afternoon, who had had his leg dreadfully mangled by a heavy waggon wheel going over it, which had produced the most severe compound fracture of the tibia, near the knee joint, besides fractures and compound dislocations of one or two joints of the toes, with much laceration of the soft parts, and had literally torn the upper end of the fibula out of its situation to the tibia at the knee. He was exhausted and delirious by the accident, and the limb was amputated above the knee by Mr. Babington in the evening. He slept well after the operation, and has gone on very well since that time till November 1st, without presenting any thing deserving especial notice.

ACCIDENTS AT THE LONDON HOSPITAL.

Mr. SCOTT, *Surgeon*.

Mr. HAMILTON, *Assistant-Surgeon*.

Oct.	Sex.	Age.	Case.
17.	M.	38	Fractured ribs.
18.	M.	45	Compound fracture of tibia and fibula.
	M.	53	Fractured radius and severe contusions.
	M.	47	Fractured ribs.
	F.	64	Inflamed arm, from punctured finger.
	F.	66	Fractured metatarsal bones.
19.	M.	21	Fractured tibia.
	F.	37	Sprained ankle.

	M.	71	Contused foot.
	M.	39	Contused neck.

In-patients 26

Out-patients 39

Total 65

(*a.*) In this case the patient had been the subject of umbilical hernia for 28 years, during which time she had constantly worn a truss, although the whole of the protrusion could not be returned. On admission, she was labouring under all the symptoms of strangulation, which had existed about twenty hours. The operation was immediately performed; the sac contained a considerable portion of adherent omentum, and beneath this a large fold of intestine. After dividing the stricture the intestine was returned, and the omentum left in the sac. The bowels were freely relieved soon after the operation, but the woman never rallied from the state of depression she was in at the time of admission, and she died in about 36 hours. Being a Jewess, no post-mortem examination was allowed.

DISCUSSION IN EDINBURGH REGARDING THE PATHOLOGICAL CHAIR.

THE College Committee reported that they were of opinion that the proposal of Dr. Thomson, to have his class taught by Dr. Simpson, might be acceded to.

The following letter from Lord John Russell, in answer to the Memorial of the Council wishing the consent of Government to the abolition of the Chair, was also read at the same time:—

“Whitehall, Oct. 16, 1837.

“My Lord,—Considering the great importance of the decision which it is my duty to form upon the Memorial of the Town Council respecting the Chair of General Pathology, I trust that it is unnecessary to advert to the delay which has occurred in forwarding my reply to it.

“As your Lordship and your colleagues do not now dispute the right of the Crown to institute that or any other professorship, the question to be resolved is, whether any circumstances have occurred since 1831, to induce the belief that the step then taken by Viscount Melbourne, upon deliberate reflection, has been attended with consequences detrimental to the general interests of the University, or injurious to the character of its medical education.

“After a careful review of all that passed on the institution of this Chair, and a grave consideration of the arguments brought forward in support of its abolition, I confess that I arrive at a different conclusion from the Memorial, and feel convinced of the soundness of the judgment which led to its establishment. And in this opinion I am supported by many most eminent and disinterested profes-

sional men. It is complained that the compulsory attendance on this class, having added to the labours of the students at the University, has, therefore, been one of the means of diminishing their numbers; though it is not asserted that it has made any great effect on the number of the graduates. I am inclined to think that the decrease in attendance being, as I take it, general throughout the University, and not confined solely to the medical classes, may be attributed to other causes than the introduction of the class of general pathology into the curriculum, viz. the existence of many other seminaries which have sprung up, and are continuing to do so daily, all over the country, and the means afforded in London and elsewhere of attaining medical knowledge.

"I view this question also on still higher grounds. The curriculum of the University of Edinburgh has hitherto given security to the public as to the efficiency of those who attain the honours of its medical degree, and it would involve her Majesty's advisers in a deep responsibility were they to consent to abolish a branch of instruction which, by all the accounts I can obtain, is daily increasing in estimation with the profession, not only in England, but generally throughout Europe.

"I will not enter into the comparison you have drawn between the curricula at Edinburgh and Glasgow, for I feel assured that on reflection your Lordship and colleagues will see, that if the Government wish to advance the interests of science, and secure to the public the advantages of high professional knowledge, their course should not be to lower the course of study in Edinburgh to the level of Glasgow, or any other Scotch University, but to endeavour to raise them to the higher standard. If, on the contrary, the argument in the Memorial were admitted to be valid, several others of the Chairs in Edinburgh should be abolished, and the cheapest education considered as synonymous with the best.

"I must, therefore, respectfully decline to comply with the prayer of the memorial; but I beg to assure your Lordship, that in so doing I am guided solely by a feeling for the cause of medical science, and the permanent welfare of the University of Edinburgh. And I deeply regret that we should differ so widely in the conclusion to which we have come to on the subject.

"I have the honour to be, &c.

"J. RUSSELL.

"The Lord Provost."

The consideration of the Report of the

Committee was first taken up, when, after considerable discussion, and the approval of the Report having been moved and seconded, Treasurer McLaren moved, as an amendment, that it be remitted to the Law Committee to consider and report, whether, considering that Dr. Thomson has twice intimated his inability to conduct the class of Pathology, and his belief that he will never be able to resume his duties, the Town Council is obliged to sanction the appointment of a substitute, or whether they are entitled to refuse their sanction to any course of imperative lectures which is not delivered by the present Professors—with power to take the opinion of Council.

Mr. Deuchar seconded the motion.

The Council having divided, 15 voted for the amendment, and 10 for the motion.

With regard to Lord John Russell's letter, after some discussion, the Lord Provost was requested to acknowledge its receipt, and to notice the error into which the noble Lord had fallen, in assuming that the magistrates and Council do not now dispute the right of the Crown to institute the Professorship of Pathology, or any other professorship. Treasurer McLaren, and other members, expressed great regret at the conclusion to which the noble Lord had come respecting the Chair, and remarked that the letter was any thing but creditable to him. This was disputed by Messrs. Laing, Ritchie, and others.

QUAIN'S ANATOMY.

To the Editor of the Medical Gazette.

SIR,

THE parts of *Hernia* are of such general interest and importance, and the want of an elementary work on anatomy, illustrating the subject by plates, has been so long regretted, that the announcement of a new edition of Quain's Anatomy was very favourably received. It was confidently hoped that Dr. Quain would not have lost sight of the necessity of simplifying, by means of engravings, the intricate parts of hernial anatomy; and as the omission must diminish considerably the sale of the work, I take the liberty of suggesting the annexation of the subject to the second volume.—I am, sir,

Your constant reader,

B.

Banbury, Oxon, Nov. 1, 1867.

ACTION OF CHLORINE ON THE
ALKALOIDS.*To the Editor of the Medical Gazette.*

SIR,
HAVING observed in your ably conducted journal the remarks of Mr. Schweitzer, on Chirayitine, Quina, &c., I write for the purpose of correcting an error into which he has fallen, in attributing to Mr. Roper those experiments on the action of chlorine and ammonia upon the alkaloids, quina and morphia. If your correspondent will refer to page 362, in the next number of the GAZETTE, he will see Mr. Roper's letter, who, acting as my amanuensis, inadvertently signed his own name. These experiments were first published in your journal of 1832, and subsequently with some additional remarks in the Philosophical Magazine, of February 1835, the date of both of which publications will be found prior to that of the more detailed account of M. André, in the Journal de Pharmacie of 1836. In conclusion, if you will have the goodness to correct a slight error in Mr. Roper's note, my name being spelt "Mason," instead of Meeson, you will oblige,

Yours most obediently,
H. A. MEESON.

Guy's Hospital,
Nov. 1st, 1837.

SIR JAMES CLARK.

HER Majesty has been pleased to create Dr. James Clark a baronet of the United Kingdom.

NEW MEDICAL WORKS.

Quain's Anatomical Plates of the Vessels. Folio, 2*l.* 14*s.*; plain, 3*l.* 18*s.*, coloured.

Rudiments of Physiology. By the late J. Fletcher, M.D., &c., 8vo. 9*s.*

Prize Thesis, on the presence of Air in the Organs of Circulation. By J. R. Cormack, M.D., 1*s.* 6*d.*, 8vo.

Dr. Bennett on the Physiology and Pathology of the Brain, 8vo., 2*s.* 6*d.*

First Principles of Medicine. By A. Billing, M.D. Second edition, 8vo. 6*s.*

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine.

By **SOUTHWOOD SMITH, M.D.**

Physician to the London Fever Hospital.

LECTURE I.

INTRODUCTORY.

Object of Medical Science not merely the removal of Disease—Available to the ends of Justice. Why Forensic Medicine is included in the Medical Curriculum.—Progress of Civilization.—Progressive value of Life.—The Medical Man the most important Witness when Murder is committed—When violence short of Murder is inflicted—When it is necessary that an individual should be deprived of the enjoyment of Social and Civil Rights—When a person is irresponsible for his actions—In all questions relating to the Public Health—Quarantine.—Factory Question.—Why it is necessary to make Forensic Medicine a distinct branch of Study.—Term proper for the designation of this branch of Science.—Precise province of Medical Witness—Of the Lawyer.—Subjects included in the field of Forensic Medicine.—Tabular View.

GENTLEMEN,—That branch of science which it is your privilege to study, and the blessings of which I hope it will be your happiness largely to diffuse among your fellow beings, does not complete its office when it mitigates the suffering of hopeless disease, or changes disease to health; nor even when, guiding the hand of the surgeon into the very inmost recesses of the body, it enables him to avert the progress of a mortal malady, such, for example, as aneurism, or at once to extirpate some malignant growth, which is incompatible with the function of a vital organ, or which, by the incessant irritation it excites, is

rapidly exhausting the powers of life. These are objects which it does accomplish, and the magnitude of the service it thereby renders to humanity is not the less, because it is rendered daily and hourly.

But there are other services which it is called upon to afford, less often, it is true, but, when the occasions for them arise, scarcely less momentous in their nature and results.

In some cases, indeed, the award of justice is more important than the removal of pain, or the cure of disease; and the vindication of innocence is a higher object even than the preservation of life itself. Before "legal tribunals, on innumerable occasions, justice cannot possibly be awarded, innocence cannot be vindicated, crime itself cannot be visited with the punishment which it merits, speaking vulgarly—with the correction which ought to be applied to it, speaking philosophically—unless medicine and surgery, and their great allies, chemistry and physiology, and several other branches of physical and vital philosophy, concur in bringing the aid of science to the administration of the law.

So strong was this conviction in the minds of a few enlightened men, and so energetically, and, after a time, so effectually, did they labour to communicate this conviction to others, that it has at length become the universal conviction. Accordingly, the authorities who have at present the regulation of medical education, have now decided that the study of medicine (using the term medicine in its largest sense,) with a special reference to its application to legal purposes, shall form an indispensable part of the medical curriculum.

Perhaps, then, I cannot more profitably occupy your time on the present occasion, than by pointing out the philosophical, the moral, and the professional grounds, on which this decision may be regarded as

wise. The statement of these grounds will afford me a fitting occasion to shew the peculiar advantages which are likely to result from the obligation under which every medical student is now placed, to give a separate and extended consideration to the subject of Forensic medicine.

In the savage state there is no institution of property, and no security for life. In the barbarous or semi-savage state, the protection of property is exceedingly imperfect, and life is correspondingly insecure. From the establishment of property result the culture of the soil—the invention of manufactures—the accumulation of capital—leisure for the cultivation of art, science, and literature—and a consequent and a continually advancing improvement in the intellectual and the moral character of man. But the blessings which thus flow from this beneficent institution, are crowned by the protection which it affords to human life, and by the value which it causes to be set upon it.

In a certain stage of civilization, the crime of murder is punishable only by a pecuniary fine. The amount of the fine affords a measure of the value of life in the estimation of the community; for the price set upon an individual's life is always determined by his rank; being great or small, according as his rank is high or low.

Two remarkable changes take place whenever, in the progress of civilization, the great institutions of property and of law become settled and secure. In the first place, rank ceases to be the standard of the comparative value of life; the rich and the poor, the prince and the peasant, the philosopher and the clown, are placed in this respect on a perfect equality. And in the second place, the value of life is so prodigiously raised, that the wilful and violent destruction of it now constitutes a crime of the highest magnitude, and is visited with the severest penalty which the collective power of the community can inflict on an individual man.

In this state of society, from the earliest infancy, the sympathies of all hearts, and the associations of all minds, are so directed by education, that the utmost terror is connected with the perpetration of the crime of murder; so that the murderer, though no human being but himself be cognizant of his guilt, is the prey of a secret remorse, such as few have been found able to sustain; while the discovery of the crime at once cuts off the criminal from all intercourse with his fellow beings, deprives him even of their pity, and induces them, without exception, with a stern and inflexible feeling of duty, to shed blood for blood—to take life for life.

But the institution of law would be use-

less, unless, when the law is violated, it were possible to bring home to the wrong-doer evidence of his guilt. In proportion as in the progress of society its institutions really become provisions devised by reason for securing justice, in that proportion is the administrator of the law careful that the penalties annexed to its violation are inflicted on no one, unless satisfactory evidence be adduced that he has really committed the crime laid to his charge; and the enormity of the offence, and the magnitude of the penalty attached to it, do but increase the demand that the proof in every case be clear, exact, and complete.

Now it happens that in almost all the cases in which life is taken away by a criminal act, some of the most important questions that arise are questions which can be satisfactorily answered only by those who are acquainted with the phenomena of life. The exact nature of injuries inflicted on the living body can be ascertained only by those who have studied the structures to which life is attached—who are acquainted with the functions in which life consists—who know the derangements which constitute disease, and the diseases which terminate in death. In the great majority of cases of this class, therefore, the medical man is the only witness in whose power it is to afford that precise and complete evidence which is required in the administration of justice. The studies to which the physician and surgeon are devoted render them familiar with the influence of external agents upon the structure and functions of the body, with the effects produced by a variety of noxious agents, and more especially with the phenomena that result from the external and the internal administration of specific poisons—the agents by which the crime of murder is generally perpetrated. Accordingly, it is upon the evidence given by the medical witness—evidence which his knowledge of subjects of this class peculiarly fits him to collect and state—that the fate of the accused, in a great measure, depends; while it is quite certain that exact knowledge of this kind is indispensable, not only to the detection of the particular poison administered in any individual case, but often also even to the discrimination of death by poison from death by natural causes.

Again, in every community in which civilization has made tolerable progress, not only is life protected with the most extreme care, but all violence wantonly or maliciously inflicted on the person, though it fall short of producing death, constitutes a crime of high magnitude. Hence the dismemberment, the disfigurement, or the disablement of the body, are crimes to which specific penalties are attached. But of the

mode in which injury of this kind has been inflicted—the agent by which it has been accomplished, whether mechanical or chemical—the probable evil consequences that will ensue—and the extent and duration of those consequences—of all this the physician or surgeon is the only competent judge, the only man who can give to the administrators of the law exactly the information they require. This, therefore, is another class of subjects in relation to which the evidence of the medical witness is constantly required in the courts of justice.

But if in the early and rude states of society the protection afforded to life itself be slight, still less care is taken to secure the enjoyment of life, by securing to each individual the means of enjoyment. Among the means of enjoyment may be reckoned especially the use of property in all its shapes, and in all the modes in which it is capable of affording pleasure, together with the exercise of various rights and privileges which grow out of the social state. Against the deprivation of any member of the community of any of these, without a paramount cause, the legislator, in proportion as he has accomplished the object of his science, has effectually guarded. But there are diseases, some of them congenital, others the result of causes which operate at various periods of life, which incapacitate the individual, both for taking care of his own property—for making it the means of enjoyment to himself, or to others—and at the same time for performing various social and civil functions. Hence arise questions relating, on the one hand, to idiocy and insanity, and on the other to impotence, to sterility, to legitimacy—questions often of the utmost delicacy and difficulty, involving the dearest interests of the human being. And with these questions of disqualification are necessarily connected questions of irresponsibility—questions of exemption from punishment, notwithstanding that actions have been committed which in themselves are subject to the heaviest penalties. On all questions of this class the medical witness is the only man who can guide the judgment of the jury and the judge—who can prevent them from misdecision; that is, who can save them from permitting, or from inflicting, the most terrible evils.

But the administrators of the law are, moreover, frequently called upon to decide questions of another kind—questions relating to the public health, respecting which they must necessarily seek for guidance from medical science—questions which involve, on the one hand, large amounts of property employed in carrying

on certain branches of manufacture, and on the other hand the salubrity of the neighbourhood in which the manufactories are situated. Certain processes carried on in these manufactories are highly deleterious, or are supposed to be so. They poison the air, or they poison the water, or they injure in some mode or other, real or supposed, the public health. Are these processes really pernicious? If so, do they admit of remedy? If they admit of remedy, what is the effectual remedy? If they admit of no effectual remedy, do they endanger the public health to such a degree as to render it indispensable to sacrifice the amount of property in question, rather than permit the far greater sacrifice implied in the injury of the public health. To all these questions, the true solution upon which alone can be formed a just legal decision, can be given only by medical science.

There are, too, several questions relating to the public health, which cannot be properly included under Forensic medicine, but which would readily find a place under a general term, of more extensive significance, such as that of State medicine. Questions of this class are, all questions relating to the salubrity or insalubrity of particular localities; the special causes of the salubrity or insalubrities of such localities; the structure of buildings with a view to health, and more especially as respects their proximity to each other, and the facility with which they admit of free and perfect ventilation; the drainage of the country, in general, and the draining of the streets and houses of the city, the town, the village, in particular; the cleanliness of houses, streets, villages, towns, and cities; the immediate removal of all putrefying vegetable and animal substances; the freshness and sound condition of provisions—vegetables of all kinds, meat, bread, flour, fruits of all sorts, water, &c. On the condition of these most important agents depends the general prevalence, or the entire absence, of a very large proportion of the diseases which afflict and shorten human life; and in particular on their condition depend most essentially, and perhaps entirely, the presence or absence of epidemic and pestilential diseases.

But even that court, which is above the law itself, and which makes the law, the High Court of Parliament, is on some occasions under the absolute necessity of seeking counsel of medical science, and counsel from this source it ought to seek on more occasions than it does. There is at the present moment one question of the highest commercial importance, which it ought to investigate anew, and in the investigation of which it ought to obtain the assistance of the best medi-

cal science it can secure, viz. the question of Quarantine regulation, respecting which there are in actual and constant operation practices formed on prejudices and absurdities worthy only of the age of witchcraft—practices which uselessly and grievously impede and fetter commerce, which cost the country, for doing worse than nothing, hundreds of thousands of pounds annually, and which tend to keep up notions which as they had their origin in the darkness of barbarous ignorance, so they are completely dispelled by the light of science—notions, the moral and social influence of which is as pernicious as their foundation, when viewed by the eye of reason and knowledge, is seen to be baseless.

I may refer to a recent example in which Parliament sought counsel of medical science, relative to a question in which vast mercantile interests were involved, in which the interests of nearly four hundred thousand of the working people of the country were equally involved, and which some of the best and some of the worst passions of our nature had alike combined to complicate and perplex. I refer to the Factory question; on which difficult question Parliament sought counsel, among other sources, of medical science, and to the essential difficulty of which, medical science afforded the solution.

On the one hand, it was asserted that the great factories of the country were the sources of wide-spreading and fatal diseases and of the most frightful vices; and on the other hand it was affirmed, that these same factories were perfectly healthful, and free from the production of any kind or degree of vice. The labour to which the infant portion of the manufacturing population was subjected, was said to be so excessive as to produce extreme physical suffering, and permanent bodily deformity and disease; and, according to representations constantly and vehemently made, this excessive labour was extorted by the most cruel punishments. On the contrary, the labour of the factory was declared to be light and easy, and in no degree excessive, and the punishment of the children was affirmed to be not greater than the chastisement which takes place in a well-regulated school or family.

The Government issued a commission to ascertain and report upon the facts of this matter. Civil commissioners were appointed to investigate more especially the bearings of the question on the great commercial interests of the country, and medical commissioners to examine more especially into the health of the factories in general, and of the infant workers in particular. On the examination of the whole body of evidence, collected by the commissioners,

it was reported that the labour, or rather the duration of the labour, of the young people was excessive, and that up to a certain age—viz. that of puberty—the labour, instead of being continued 12 or 13 hours per day, as was the case at that time, should be restricted to eight hours per day: at the same time a method was suggested, viz. that of working by two sets of children, instead of one, by which the requisite restriction might be imposed upon the labour of the children, without interfering, in any material degree, with the labour of the adult. The plan suggested by the commission was adopted by the legislature, and the law, now that obedience to it is enforced, is found to accomplish the purpose for which it was enacted. In all the factories in the country the essential principle is recognized and obeyed, which before the labours of the commission was maintained to be impracticable, viz. the separation of infant from adult labour; the expediency of placing a legislative restriction on the former, and of leaving the latter entirely free; and the concurrent testimony of all classes shews that the statute, founded on these principles, gives, upon the whole, satisfaction to all parties; to the operative no less than to the mill-owner; while the public clamour, consisting partly of truth and partly of falsehood, and raised partly from benevolence, but far more from sinister and selfish motives—that clamour which had so long fostered discontent among the work-people, and impeded the operations, and even endangered the capital of the manufacturers, has been completely silenced.

If, however, we restrict our view, which we must necessarily do on the present occasion, to the subjects which fall properly within the province of Forensic medicine, we shall find that the information which the judges of the law require of the medical witness, is spread over almost the entire field of medical and surgical science. Anatomy, which teaches the structure of the body; physiology, which investigates its functions; semeiology, which makes us acquainted with the symptoms that denote a morbid condition of those functions; pathology, which instructs us in the changes of structure produced by disease; chemistry, which enables us to detect, under all its disguises, the presence of any deleterious substance in the body; and toxicology, which teaches us the special action of the entire class of poisons; all contribute their aid, each in its peculiar mode, to save the administrators of the law from error, and to guide them to a just decision.

But you will say, these branches of the medical science constitute the entire sci-

ence ; why, then, make a distinct branch of study of what must necessarily be included in the general study of medicine? This is a natural question, and the answer to it will place in a still clearer light the nature and object of our subject.

You may make yourselves thoroughly acquainted with every branch of your art and science required in ordinary practice ; you may know promptly and accurately what to do for the benefit of your patient, under the ordinary circumstances of disease, or even in a case of sudden and great emergency ; but a case falls under your notice—a suspicious or a criminal case—a case involving life and death, respecting which you are required to give evidence in a court of justice. Here, new, unexpected questions arise—questions which the court requires to be solved with clearness, accuracy, decision—questions which no one who is not familiar with the more abstruse and difficult points of your science can possibly answer. You may really know all that is necessary to the formation of a clear and just opinion on this judicial case ; you may not be positively ignorant of a single fact or phenomenon, the knowledge of which is requisite to the decision of the matter in hand ; and yet, without some previous consideration, perhaps even without some close study, it may be impossible for you to bring what you really know to bear with the requisite precision and force on the point in question.

In a court of justice, too, you are placed in a new situation. Questions are presented to you requiring to be answered promptly, distinctly, decidedly, accurately—questions which now come to you in a new shape : not like questions proposed to you by persons as well acquainted with your profession as yourselves, but questions proposed by persons wholly ignorant of your profession. Such persons have difficulties which you never before understood—indicate doubts and uncertainties which had never occurred to you. They call upon you in the most solemn and earnest manner to resolve those difficulties—to set at rest those doubts. But if the matter in hand have been considered by you only generally, vaguely, loosely, now, at the very moment when you are called upon to decide on professional responsibility, on the stake of your own professional reputation—difficulties and doubts may for the first time come into your own minds. There may be no real difficulty—no ground for doubt. There may be difficulty—there may be good ground for doubt. Ought I to give a positive opinion? Ought I to give a restricted and guarded opinion? This thought occurs to you—you do not feel sure—you hesitate. All eyes are on you. The

barrister urges—urges you for a positive answer. The judge scrutinizes not the words only that fall from your lips, but the mind that dictates them—the intelligent, instructed, decided, trustworthy mind, or the ignorant, uninformed, hesitating, and untrustworthy mind. You are profoundly conscious of all this. The probable consequence is, that you stand there, before highly intelligent and deeply interested spectators, professing to be a man of science—appearing there for the express purpose of bringing your scientific knowledge to bear on a particular point for the guidance of justice ; yet there you stand confused, unable to connect your ideas, still more unable to express them—bitterly feeling in your own heart, and exciting the resentful feeling in others, that you throw perplexity, confusion, and darkness, on that which you were called upon to disentangle, and to set in a simple, clear, and practical light.

It is singular that perhaps the very greatest mind, at least in particular departments of our science, which our country has ever produced, was once placed in a situation in a court of justice, scarcely less humiliating than that which I have just supposed. I allude to no less a person than John Hunter. That illustrious man was called to give evidence in a court of justice, anterior to the period when any general attention had been paid to the subject of Forensic medicine. The case on which he was examined as a medical witness, was one of great importance. He ventured into court without having taken the precaution to examine the point on which he was to speak with scientific exactness and conscientious care. The consequence was that the cause of truth and justice, as far as that cause was capable of being affected by his evidence, was endangered, and his great and deserved reputation could not protect him from the severe animadversion of others at the time, nor save him subsequently from his own self-reproach.

Mr. Hunter was called to give evidence as to the operation of a particular poison in the case of Captain Donegan. To this remarkable case I shall have to recal your special attention, for another reason, at a subsequent lecture. It was presumed that this great physiologist must be well acquainted with the action of poisons on the animal economy. On this presumption he was summoned to give his assistance in the present case. In what manner did he perform his office? What was the impression made by it upon the minds of those who were called upon to consider its weight and bearing. Hear what the judge who presided on the trial said of it in his

address to the jury:—"You have had," says his lordship, "one gentleman called, who is of the faculty, and a very able man. I can hardly say what his opinion is, for he does not seem to have formed any opinion at all in the matter. He at first said he could not form an opinion whether the death was or was not occasioned by the poison, because he could conceive it might be ascribed to other causes. I wished very much to have got a direct answer from Mr. Hunter if I could, what, upon the whole, was the result of his attention and application to the subject, and what was his present opinion; but he says he can say nothing decisive."

This is the account of the matter given by the judge. The case, as recorded, is so clear, that I take it, as you will see hereafter, as an example of satisfactory circumstantial evidence. His own regret (as we are informed by Sir Astley Cooper) at the position in which he allowed himself to be placed, terminated only with his life. "He found himself (says Sir Astley) a good deal embarrassed on the occasion—the lawyers took advantage of his embarrassment, and he used to express his regret publicly in his lectures, that he had not given more attention to the subject, before he ventured to give an opinion in a court of justice."

Thus has the most distinguished man in our profession left upon record a lesson taken from his own experience, which we ought none of us ever to forget.

How different your situation if you enter the court with a prepared mind—prepared by study—that is, in possession of accurate knowledge, all the bearings of which you have carefully and thoroughly considered: your appearance then will be collected and calm, your replies plain, concise, clear—your language that of common parlance, so free from technicality that it will suggest to your hearers that you have considered their situation, that you have supposed them to be unacquainted with the subject, and that your single aim has been to put them in possession of all that is really known about it. If a question in explanation be asked you, it will be the means of exhibiting, in a clearer light, the precision and accuracy of your knowledge. If counsel impugn your fact, it will afford you an opportunity of adducing the evidence of it. If he question your inference, it will but afford you an occasion to show in a more striking manner that it is a strictly legitimate one. If he carp at your language, it will enable you to bring out what is in your own mind with greater exactness and impressiveness.

No one can doubt that it is possible to do all this. No one can doubt that it is

desirable to do it. No one who, both for his own interest, for the honour of his profession, and for the common advantage of the community, would not wish to see himself in the latter rather than in the former position.

Well, nothing is more easy. There is commonly no real difficulty in judicial questions; no reason why every medical man should not appear with as much honour before an assembled multitude in a court of justice, as he does with the approval of his own conscience at the bedside of the sick. The main subject with which he has to deal is the same; it is the view which he is to take of it only that is different. He is able promptly and effectually to relieve the sick, because he has studied the resources of his art in relation to the phenomena of disease. Let him but study the resources of his science in relation to the wants of the administrators of the law, and he will appear with as much dignity in a court of justice as he does with usefulness at the bed-side of the diseased.

Suppose, for example, that you study the different branches of this science with a special reference to all the main questions upon which you can be called to give evidence in a civil or criminal court. Then every one of these branches will present itself to you in a new aspect—*anatomy, physiology, semeiology, pathology, chemistry*;—there is not one of these departments of your science which you do not now view in a new light—which does not receive a new direction, and consequently which does not produce new results, and those of the highest importance, to the very best interests of the community. What, for example, does the science of semeiology become to you now? That by which you ascertain, with clearness and exactness, the difference between the symptoms of poisoning and the symptoms produced by natural disease. What the science of pathology? That by which you distinguish the appearances in the dead body that indicate death by poison from those that indicate death by natural causes. What the science of chemistry? That by which you are enabled to discover the exact poison that has been administered; and often, from its state of solution in vegetable and animal mixtures, to exhibit it pure, and even in the solid form, to the naked eye. What the science of physiology? That by which you are enabled, by means of direct experiments on animals, to settle by analogy doubtful questions relative to the operation of poisons on man.

The use, then, of separating Forensic medicine from every other study, and of erecting it into a distinct science is, that

it embodies into one condensed and well-ordered whole, the information which is spread over a vast and diversified space. Ranging over the entire field of medical and surgical science, the science thus formed collects from innumerable sources facts and principles, which by no other means could be viewed in combination; from the resources of one branch it supplies the deficiencies of others; by means of one it tests the accuracy of another; and the whole mass of knowledge which it thus accumulates from every tributary source, it pours in one direction, with a precision and force worthy of its object—the detection of crime, and the vindication of innocence*.

Various names have been proposed to designate the science which, in this manner, has for its object the application of the different branches of medical science to the administration of justice. Medical jurisprudence is one: as bad a name as could be well devised, for it does not concern the knowledge of law as applicable to medicine, but the knowledge of medicine as applicable to law.

Perhaps the least objectionable and the most definite designation of it is the name which now seems to be superseding every other, viz. Forensic medicine. The term medicine being understood in its largest sense, this name will then signify medicine capable of application in the forum, or in a court of justice. It is not, then, a branch of medicine, but the application of every branch of medicine, which is capable of such application to a legal purpose.

The term State medicine is less definite, though more extensive; for this name comprehends Forensic medicine, and something more, namely, whatever the science of medicine is capable of contributing towards the conservation of the public health.

But by whatever name we designate this application of medical science, it is of great importance to perceive clearly its precise object. It does not include, as the term medical jurisprudence would appear to indicate, two widely different subjects, medicine and law. In the application of medical science to a legal purpose, the functions of two sets of professional men, the physician and the lawyer, are indeed brought into operation; and perhaps it will help to place the subject in a clearer point of view, if we consider the exact nature of the work which each of these professional men has to do—if we define the limit

which separates the portion of the field occupied by the one, from that occupied by the other.

In relation to every case which he is required to investigate, or upon which he is called to give evidence, the medical witness has two things to do: 1st, he has to furnish the tribunal with certain facts; and next, to state the inference which in his judgment the facts warrant. It is a case, suppose, of alleged poisoning. There are certain symptoms during life. Are those symptoms sure indications that poison of some sort has been administered? Might they on the contrary have been produced by natural disease? Certain appearances present themselves on the inspection of the body after death. Are those appearances unquestionably the effects of poison, and if so, of what poison? Or are they the products of disease, and if so, of what disease? A substance of a suspicious nature is found in the alimentary canal; its physical and chemical properties, when tried by their appropriate tests, what do they declare it to be? Is it poison, or is it no poison? If it be poison, what poison is it? No deleterious substance is appreciable by the eye in the alimentary canal; but the contents of the stomach and intestines are analysed; the analysis yields a product of a suspicious nature; on further investigation this suspicious substance turns out to be one of the corrosive poisons. This is established by chemical tests. Well, the invaluable light which chemistry has now shed on this subject, does it agree with the indications already afforded by the semeiology of the case, or by the pathology of it; or may further light be thrown upon it by any physiological investigation?

Such is the nature of the inquiries which it is the office of the medical witness to pursue; and exact answers to which it is his duty, as far as it is in his power, to find. And why is he specially called upon by the judges of the law to furnish answers to questions of this class? Because he, beyond any other man, is qualified to give correct answers. On all subjects of this kind he is what in the language of jurisprudence is termed a skilled witness; his peculiar knowledge enables him to give the judges precisely the information of which they are in search. On all the subjects that come before them, what the judges want are correct answers to certain questions; and they always seek, or ought to seek, for such answers from the best sources at their command. And the variety of sources from which it may be necessary occasionally that they should seek information, is well illustrated by the following case:—

Near the Place St. Michael, at Paris, op-

* See Christison on Poisons.

posite the Rue St. Hyacinthe, there lived a woman, a widow, who kept a small shop, and slept in a little room behind it. She passed among her neighbours as being rich, and was supposed to have considerable sums of money in the house. Her only domestic was a lad, who slept in a room three stories above the shop, the stairs to which had no communication with the part of the house in which his mistress resided. In order to reach his chamber it was necessary to go into the street. When the boy went to rest, his mistress herself always closed the door of the shop after him; and locked it, and kept the key in her own possession. One morning the shop door was observed by the neighbours to be partly open; yet neither the boy nor his mistress was stirring. On examining the door it had no appearance of having been broken open; but on entering the house they found the widow lying dead in her bed; the body was covered with wounds, which had been inflicted apparently by a knife that lay stained with blood in the midst of the room. The dead body contained in one hand a small quantity of hair, apparently torn in the struggle from the head of the murderer; while the other grasped a portion of a cravat. Near the bed was a coffer, which had been forced open. Suspicion fell upon the boy. A locksmith was employed to examine the lock of the door; he proved that the lock had not been forced; the key was found in the bed-room of the boy. A hairdresser was employed to compare the hair in the hand of the murdered woman with the hair of her servant; the hairdresser pronounced it to be the same. The washerwoman who had been in the habit of washing the boy's linen, was employed to examine whether the portion of cravat found in the other hand of the dead body, was similar to the cravats worn by the servant; she was of opinion that it was perfectly similar. A well-known companion of the lad was called to state whether the knife found in the room had ever been seen by him in the possession of the accused, and whether he believed it to be his; he declared that such was his belief; and lastly, a surgeon was employed to examine the wounds, who stated that they were certainly inflicted by a sharp cutting instrument, and that without doubt of such wounds she died.

Now in this case you see the information afforded the judges was derived from five different sources, of which the medical evidence formed one. Each of these deponents was a skilled witness: each was capable of giving correct information on a particular point. In relation to questions

of this class, the medical witness is generally capable of giving exact information on numerous points, and those of the very highest importance; he is capable of furnishing certain facts, the very facts wanted by the administrator of the law, in order to enable him to form a just decision. So much, then, for the first duty of the medical witness; that of affording to the jury and the judge the facts they need to guide them to a just conclusion.

But besides certain facts which it is the part of the medical witness to ascertain, collect, and state, he has another duty to perform, of equal magnitude, and, if possible, of still deeper responsibility; for, in the second place, he has to declare the inferences which he believes to be deducible from the facts which he has ascertained. The nature of this duty, and the consequences that result from the manner in which he performs it, appear to me to be illustrated in a very striking manner by a case, the details of which were told me by one of the judges of the Justiciary Court of Scotland, who happened, on the trial in question, to be the presiding judge.

Two men in a cottage quarrelled. A scuffle ensued. One of the men was killed. The quarrel originated, there was reason to believe, in the predetermination of the survivor, who was resolved to excite it; and who, it was proved in evidence, had a deep and rooted ill-will against the deceased. The body was examined judicially by no less than six medical men. A wound was found toward the back part of the head. Two questions were to be decided: First, was this wound the cause of death? Secondly, was it produced by a fall on the floor, or was it inflicted by any kind of weapon? If produced by a fall on the floor in the scuffle, it was a case of manslaughter; if inflicted by a weapon, it was murder. All the medical witnesses were agreed that the wound was the cause of death; five out of the six stated that it might have been produced by a fall on the floor; the sixth declared that in his opinion this was impossible; for, on a most careful examination of the exterior of the wound, as exhibited in the integuments of the head, in the bone of the skull, and in the brain, he was satisfied that it was produced by some pointed body capable of piercing through all these substances; and that if occasioned by a fall on the floor, it could have happened no otherwise than by the striking of the head against some sharp body sticking up out of the floor, such as a nail. At the time of the event the floor was carefully searched; no such body could be found. On the other hand, no weapon could be discovered in the

room or about the person of the defendant, by which he could have inflicted such a wound.

Now the life or death of the defendant in this case depended on the inference drawn by the medical witnesses, from a fact obvious to their senses. The inference drawn by one was opposed to the inference drawn by five. In the mind of the judge who presided at the trial, accustomed as he was to evidence, there was, indeed, not the slightest doubt that the inference of the single witness was the correct inference. But the inference of one skilled witness could not be taken in opposition to the inference of five presumed to be equally skilled. The man was acquitted of the charge of murder.

After the trial he confessed that he went into that room determined to have his revenge, and that in the scuffle he snatched up the snuffers, the sharp point of which he struck with all his force on the head of his enemy. It had penetrated through the bone of the skull, and gone deep into the brain.

It is scarcely possible to conceive a case which places in a stronger light both the nature of the duty of the medical witness, and the care with which the duty should be performed.

The result of this trial to the single medical witness, whose sagacity had enabled him to detect the truth, is worthy of notice. It was a trial that excited great attention. The presiding judge had been struck with the clearness of mind, the patient, cautious investigation of this medical witness: he often spoke of it to the magistracy and others by whom he was surrounded; and the consequence was, that this medical man soon found himself in possession of the confidence of the best educated and influential people of the neighbourhood.

What the law is it is without doubt highly desirable that the medical man should know, as it is desirable that he should be acquainted with every thing that is to be known; but of the applicability of the facts which he states, and of the inferences which he deduces to the rule of law, this it is for the tribunal, not him, to determine; and as a medical witness, either with the fact of the law, or with the bearing of his evidence upon it, he has nothing whatever to do.

And in like manner as the medical witness has no concern with the law, so the lawyer has no concern with the medical fact, or with the medical inference, excepting it be to extract, in the fullest and most perfect manner, the entire medical evi-

dence, to examine its trust-worthiness, and having decided on that to apply it to the rule of law. "It is my opinion," says the medical witness, "that such a blow has been inflicted, and that it has been followed by such a consequence; for my experience has taught me that such is the sequence." And if there be no adverse evidence, if the statement of the medical witness agree with the statement of other medical witnesses, the lawyer must take this statement as the true statement. The lawyer's experience will not allow him to affirm that the sequence stated by the medical witness is not the true sequence; he must therefore receive it as the true one, and to the aggregate facts of which this sequence is a part he must apply the law.

Clearly, then, do you now see the exact province of the medical witness, and the exact province of the administrator of the law. And what is the impression forced upon the mind by this view of their relative duty? An impression of a responsibility attaching to the medical witness, that is, I had almost said, appalling. The lawyer has merely to draw out, merely to elicit the evidence of the medical witness, to sift it, to weigh it, and then to determine its applicability to an appointed rule; but the facts themselves, the inferences deducible from those facts, that is, the material with which the lawyer deals, all this the medical witness has to furnish.

It would be idle to say any thing with a view to enforce the obligation under which this position and office place you as medical witnesses, to prepare yourselves fully for the performance of your duty. I will only add a word relative to the subjects which require your special study, and the consideration of the most important part of which will be included in the present course.

Every thing in relation to which you can be called to give evidence in a court of justice, must relate either to the extinction of life—to the infliction of personal violence, without the extinction of life—to disqualification for the enjoyment of social and civil privileges, and the exercise of social and civil functions; or to irresponsibility for the commission of acts which the legislature has pronounced criminal.

Life may be extinguished either by purely physical causes, or by intentional human agency.

The extinction of life by causes purely physical includes all the causes of sudden death, whether from internal diseases or from external agents.

The extinction of life by intentional human agency, includes poisoning, suffocation, wounds and bruises, suicide, fœticide, infanticide,—includes all cases of this sort when brought about by human purpose.

The infliction of personal violence without the extinction of life, includes the dismemberment, the disfigurement, and the disablement of the body; rape; corporal punishment; together with injuries sustained in consequence of unskilful surgical operations, and improper medical treatment.

Disqualification for the enjoyment of social and civil privileges, and the exercise of social and civil functions, relates either to physical or to mental disqualifications. Physical disqualification relates especially to disqualification for marriage, and includes the subjects of impotence, sterility, and legitimacy; while mental disqualification includes the extended and most important subject of insanity, in all its forms and degrees; together with the distinct, though closely related subject, of irresponsibility.

In this table is brought into one view the main divisions of this portion of the field of knowledge.

I.—EXTINCTION OF LIFE.

1. Physical causes.
 - Internal diseases.
 - Sudden death.
 - Apparent death.
 - External agents.
2. Intentional human agency.
 - Poisoning.
 - Hanging
 - Drowning
 - Suffocation
 - Pregnancy.
 - Parturition.
 - Birth.
 - Fœticide.
 - Infanticide.
 - Snicide.
 - Wounds, &c.

II.—PERSONAL VIOLENCE WITHOUT THE EXTINCTION OF LIFE.

- Dismemberment.
- Disfigurement.
- Disablement.
- Rape.
- Corporal punishment.
- Unskilful medical treatment.
- Unskilful surgical operations.

III.—DISQUALIFICATION.

- Physical.
 - Impotence.
 - Sterility.

- Legitimacy.
- Age, &c.
- Mental.
 - Idiocy.
 - Insanity, &c.

IV.—IRRESPONSIBILITY.

Gentlemen, it is singularly fortunate for the interests of the community, that while on the one hand the very nature of medico-legal investigation precludes the possibility of its being pursued by any but a scientific man, and while, on the other, none but a person of skill, trained to observation, and exercised in the practice of discrimination, is competent to notice and record the moral evidence, so these two qualifications are combined in the well-educated medical practitioner. Without scientific attainment he is unfitted for any part of his profession, while his situation about the patient places him in the best position for observing and collecting the moral evidence; he sees all the parties in the first instance, comes into intimate communication with them; no look, no attitude, no expression, whether voluntary or involuntary, whether accidental or designed—no action can escape the notice of the acute and enlightened medical practitioner.

Your assumption of the character of well-educated medical men is a contract which you enter into with the public, that you will gain the information necessary to enable you to perform with promptitude and skill the various duties of your profession. When they consult you, they do so in the confidence that you have fulfilled your part of this contract. In a judicial case more especially, they will never forgive—they never have forgiven—any detected betrayal of this confidence, whether such betrayal were the result of ignorance or of indolence. Be your previous reputation what it may, you will lose all character for ever, if once, in a court of justice, before the eyes of intelligent and deeply-interested spectators, you indicate incompetence. To this subject appear to me to apply with peculiar force the words in which one of the most honoured and revered teachers of our day was accustomed to conclude his introductory lecture on anatomy. Those words have always appeared to me not memorable only, but deeply affecting. "In other professions," says the late Dr. Baillie, "indolence may be a folly; in ours it is a crime!"

ON THE
PRACTICAL INFERENCES
WHICH RESULT FROM
SOME LATE PHYSIOLOGICAL
INVESTIGATIONS
RESPECTING THE
LAWS OF THE VITAL FUNCTIONS
IN THE MORE PERFECT ANIMALS.

By A. P. W. PHILIP, M.D. F.R.S.L. & E.
Fellow of the Royal Colleges of Physicians
of London and Edinburgh, &c.

To the Editor of the Medical Gazette.

SIR,

It is a remarkable fact,—but on comparing the whole of the evidence it will, as far as I am capable of judging, be found undeniable—that, in the present advanced state of medical knowledge, a cause of many of the most formidable diseases to which we are subject is in constant operation around us without attracting our attention, till its consequences are such as often defy the most assiduous application of our art. If such be the case, it is evident that the error must be deeply seated. It can have no other foundation than a mistaken view of some of the fundamental laws of our constitution.

It will appear, I think, from the facts to which I shall refer, that we are constantly meeting with cases in which the fatal result might have easily been averted, had we been more early aware of the nature of the change which had for a long time been imperceptibly, but with certainty, tending to such a termination.

I shall, in the first place, inquire what errors have existed in our views of the animal economy which may be supposed capable of such effects; then enumerate the proofs that such have been their effects; and in the third place, point out the means of detecting them before they have arrived at their necessarily fatal stage; concluding with a statement of the general principles of the treatment by which their progress may be arrested.

ALL the facts to which I am about to refer, as well as the manner in which they necessarily influence our views respecting the more important vital

functions have, in different publications*, been laid before the public from time to time, as it appeared to me that any addition had been made worthy of publication; but those relating more particularly to the subject of this paper have never been selected and reviewed in that order which is necessary to place the practical inferences from them in a sufficiently connected point of view.

I mean the present and following papers to answer the same purpose respecting the practical department of the subject, which is answered respecting the physiological, on which the practical department is in a great degree founded, by the last of the papers just referred to, in which the Royal Society, although in opposition to their usual proceedings, did me the honour to republish various statements which had, during more than twenty years, from time to time appeared in their Transactions, while the inquiry was going on; in order to place, in one point of view, the whole of the facts, and thus enable us to arrive at the conclusions which necessarily result from them, when an opportunity is afforded of comparing them together.

The physiological part of the subject was laid before the Royal Society, because physiology forms a branch of general science; and although one of the foundations on which practical medicine rests, does not, like the subject of the present paper, exclusively belong to our profession.

The physiological object I had in view, namely, to remove the various contradictions which, in some of the most essential points, obscured our knowledge of the general laws of the animal economy having, in the manner pointed out in the paper just referred to, as far as I am capable of judging, been accomplished; it only remains for me to pre-

* Various passages in twelve papers, published in the Philosophical Transactions in 1815, and succeeding years, particularly in the papers published in those Transactions for the years 1833, 1834, and 1836—the two first, on the Nature of Sleep and Death, and the last being a general review of the Functions of Life, with the inferences which necessarily arise from it: my Experimental Inquiry into the Laws of the Vital Functions, 3d edition; the Introduction to my Treatise on Fevers and Inflammations, 4th edition; my Treatise on Indigestion, 7th edition; that on the Means of Preserving Health; that on the Effects of minute doses of Mercury in restoring the Functions of Health; my Gulstonian Lectures, delivered before the College of Physicians in 1835, &c.

sent, in a connected form, the practical inferences which necessarily arise from a correction of the physiological errors; and point out how strikingly these inferences correspond with what we are constantly in the habit of observing in actual practice; for to the same inferences, we shall find, we are equally led by correct physiological views, the phenomena of disease, and the effects of our remedies.

It will be generally admitted that, except as far as it depends on the simple principle of employing the means, more frequently suggested by accident than reflection, which had been useful in similar cases; the practical part of our profession rests wholly on our knowledge of anatomy and physiology, a knowledge of the structure and functions of the animal body.

From the first of these sources (independent as it is of previous knowledge, and exercising only the simplest faculties of the mind) all practical knowledge of the healing art possessed in the rudest state of society is derived. As the limited nature and uncertainty of such a source appear, we are led to the means of assisting it.

We by degrees perceive the necessity of distinguishing the local and general, and the more immediate and remote, effects of our remedies; and soon find that to make any considerable progress in such investigations, some knowledge of the structure and functions of the subject of our practice is necessary; and that in proportion as this knowledge is acquired, our means of relief become more effective.

When I entered on the investigations just referred to, all our doctrines, as far as respects the general laws of our frame, were involved in a confusion which none of the facts, of which we were in possession, enabled us to unravel. I therefore began by repeating many of the experiments of the physiologists who had for their object the elucidation of those laws, at the head of whom I found Haller, Le Gallois, and Hunter. I found the results of their experiments such as they state them to be; but the inconsistency of their inferences left no room to doubt that some of them are fallacious; which will not surprise us when we consider the state in which they found the subject; for any thing that had been done re-

specting the general laws of the animal economy before their time was comparatively of little account, being in most instances either so evident as not to require the aid of experiment, or erroneous.

It had, however, the merit of being to a certain degree consistent—a consistency not difficult of attainment, because, as the test of direct experiment had been little resorted to, it was easy to make any supposition which was necessary towards attaining it; but after the time of Haller, who may be regarded as among the first of those physiologists who applied with any accuracy to physiological inquiries the principles of inductive reasoning, the dreams of the older physiologists began to share the fate they so justly deserved, and the consistency of our systems immediately began to suffer.

The few facts at first ascertained were stubborn things, and would not conform to the loose and fanciful theories which had prevailed. Thus difficulties arose, and, even so lately as at the time my labours commenced, prevailed to so great a degree, and caused such confusion in our doctrines respecting the general laws of our frame, that some despaired of seeing it effectually removed.

If, as appeared from the experiments of Haller, the power of the heart is independent of the nervous system, and this organ is incapable of being influenced through its nerves; how comes it to be subject to the passions? and how comes it, as M. Le Gallois proved, that its power may be destroyed by crushing the spinal marrow? Whence does it arise, as appears from the experiments of the latter, that the sudden destruction of a part of the spinal marrow impairs, and may even destroy, the function of the heart, while the destruction of the same part of the former organ by small portions, in no sensible degree affects its power? How comes it that the affections of the mind so powerfully influence the heart, when the total removal of the brain, as proved by M. Le Gallois, does not even in the slightest degree influence it? Why, if the power of the heart depends on the spinal marrow, as it appears to do from the experiments of M. Le Gallois, the accuracy of which I have ascertained by repeated trials, have fetuses been born alive, where no spinal mar-

row had ever existed? or why, if the power of the heart depends on the spinal marrow, does it continue to perform its usual motions after it is removed from the body? Why, if, as M. Le Gallois maintained, all vital organs bear the same relation to the nervous system, is the function of the heart uninfluenced by dividing the eighth pair of nerves, or even by decapitation, and that of the stomach and lungs impaired by dividing, or even by throwing ligatures round, these nerves? Why do the motions of respiration cease on the destruction of the medulla oblongata, since the nerves of the muscles employed in respiration arise from the spinal marrow, which M. Le Gallois proved by experiments, the accuracy of which cannot be questioned, to be capable of exciting the muscles which derive their nerves from it, independently of that and all other parts of the brain? M. Le Gallois points out this inconsistency, and admits that he sees no means of removing it.

However accurately detailed the results of the experiments, such contradictions left no room to doubt the inaccuracy of some of the inferences. It was evident that while many facts of importance had been discovered, others of a leading nature must have been overlooked, the discovery of which alone would remove the foregoing inconsistencies, and afford any useful knowledge of the general laws of our frame.

It was with this view that the investigations in which I have so long been engaged were undertaken. As the object of the present paper is wholly of a practical nature, I shall not enter into physiological discussions, but merely point out the manner in which the results of my experiments have effected their object, referring to the *Philosophical Transactions*, and my *Experimental Inquiry into the Laws of the Vital Functions*, for the detail and application of the experiments.

The following are the positions ascertained by the investigations referred to, by which the difficulties above detailed are removed, and the general laws of the animal functions reduced to that simplicity which is always observed in the works of nature, when a correct knowledge of them is attained:—

It is true that the heart, as ascertained by Haller, cannot be influenced through

its nerves in the same way as the muscles of voluntary motion; not from the heart being placed beyond the influence of the nervous system, as he supposed, but from that influence being conveyed through nerves of different properties from those by which it is conveyed to the muscles of voluntary motion; for in our frame, beside the nerves of sensation and those of motion, there is a third set—the ganglionic nerves, the functions of which we shall find are as different from those of both these sets of nerves, as their functions are from those of each other*.

It is true that in destroying the spinal marrow, the effect on the heart is so essentially influenced by the manner in which this is done, that its function may either be instantly destroyed, or, as far as we see, in no degree affected by it. But this arises not from the cause to which it is ascribed by M. Le Gallois—a cause which has no existence†—but we shall find is a consequence of the heart being placed under the influence of every part of the spinal marrow, from that by which it is united to the brain, to its extremity at the lower end of the spine‡.

The heart, we find, is uninfluenced even by the removal of the whole of the spinal marrow, because, in direct opposition to the inference of M. Le Gallois, its powers are wholly independent of this organ; but while the nervous connexions are entire, the heart is placed under the influence of every part of it. The same observations apply to the brain: its influence on the heart is not confined to any particular part, but extends to every part of it. The heart may be influenced through whatever part of either the brain, properly so called, cerebellum, or spinal marrow, provided the agent operate on a considerable portion of any of these organs; for if confined to a very minute portion, it makes no sensible impression on the heart§, which, being influenced by every part of the former organs, feels not, in an observable degree, the effect of an impression made on each minute portion of them. Hence it is that the sudden destruction of any considerable

* *Philosophical Transactions* for 1829 and 1836.

† *Experimental Inquiry into the Laws of the Vital Functions*, Part I. When this Inquiry is referred to, it is always to the third edition.

‡ *Philosophical Transactions* for 1829 and 1836; and *Inquiry into the Laws of the Vital Functions*, Part II.

§ *Inquiry*, &c. Part II.

portion of either may destroy the function of the heart, while its slow destruction—that is, by a succession of minute parts—may not at all sensibly affect it. From the whole of the facts here referred to, it arises that the heart is uninfluenced by the removal of either the brain or spinal marrow, or even of both at the same time; but while the nervous connexions remain entire, it may, through any considerable part either of the brain or spinal marrow, be excited, and that to any degree of which it is capable, or wholly deprived of power, according to the nature of the cause operating on a considerable portion of those organs, and the extent of the part subjected to its immediate operation.

We now see why, although the heart is subjected equally to the power of the brain and spinal marrow, its vigour may have been perfect where neither organ had ever existed; for fœtuses have been born well grown, and in other respects of the usual size, without either brain or spinal marrow, an instance of which I have witnessed*; the power of the heart, though influenced by, being wholly independent of, both. Thus also it is still capable, as we have seen, of performing its usual motions after it is removed from the body. All the preceding observations apply to the vessels as well as to the heart. The motion of the blood in the vessels, with the exception of the arteries, in which it feels the impulse given by the heart—that is, in the capillaries and veins—depends on their own powers alone, being wholly independent of the heart; and the relation of their powers to the brain and spinal marrow is in all respects the same as that of the heart itself.†

The different vital organs are differently affected by being deprived of the influence of the brain and spinal marrow, because the nature of the functions performed by that influence in them is wholly different. The brain

and spinal marrow, we have just seen, bestow no power on the heart and blood-vessels: they both derive their power from the muscular fibre; a power, whether with respect to the muscles of voluntary or involuntary motion, wholly independent of, though subjected to, the influence, of both the brain and spinal marrow‡; while the powers of the other vital organs—the stomach and lungs, for example—except as far as they depend on the mere muscular power, are wholly dependent on the brain and spinal marrow†. The stomach will never secrete a particle of gastric juice after it is deprived of the influence prepared by the brain and spinal marrow, nay, after it is deprived of that of either; and will not secrete a perfect gastric juice if deprived of the influence of any considerable portion of either; and the same observations apply to the chemical changes which take place in the lungs‡: nor is this all, for if a considerable portion of the influence of either be withdrawn, the structure as well as function of all secreting organs will sooner or later, according to the degree in which that influence fails, be impaired§; and if the cause of failure be very powerful, or of long continuance, wholly destroyed||.

It thus appears that the brain and spinal marrow supply an influence on which not only the power of secretion but the whole of the assimilating powers depend.

Through what channel is this influence, on which the functions of life so immediately depend, conveyed?

Anatomy, with the aid of the physiological experiments on which this paper is founded, affords a ready reply. The ganglionic nerves, according to the sense in which I have used this term¶,—that is, the nerves which either enter or send branches which enter those ganglions which receive nerves from different sources, and the nerves which proceed from such ganglions. These may justly be termed the nerves

* From such instances, compared with the facts to which I am about to refer, we have reason to believe that the vital organs of the brain and spinal marrow, like the lungs, are inactive in the fœtal state; and that their functions in this state, like the functions of the lungs, are effected by the powers of the mother.

† My paper on the Sources and Nature of the Powers of Circulation, in the Phil. Trans. for 1831. It occasionally, though rarely, happens, that the impulse of the heart extends to the capillaries, but this is always indicative of a morbid state of the vessels.

of life, for on the influence they convey the formation and maintenance of all our organs depend.

It cannot be without surprise that we learn that, in the present advanced state of medical science, the functions of these nerves, as far as life is concerned the most important of our frame, should have remained unknown; those of the nervous system, properly so called, having been supposed to be confined to the functions by which it administers to the sensorial powers. Such alone are those ascribed to it even in our latest and best accounts of the present state of the profession*. As we have remained in ignorance of the functions of the vital organs of the brain and spinal marrow, and indeed of the existence of such organs, and consequently of the influence prepared by them, and conveyed by the ganglionic nerves; that the failure or other morbid states of that influence should have been overlooked, is only a necessary consequence. It is on this, we shall find, is founded the position stated in the commencement of this paper; which, however unlooked for it may appear, is not the less correct—namely, that a cause of many of the most formidable diseases to which we are subject, is in constant operation around us, without attracting our attention till its consequences are such as too often defy the most assiduous application of our art.

Only one of the inconsistencies above stated remains to be considered, which has its origin in no serious attempt having been made to draw the line of distinction between the sensitive and vital functions—namely, that pointed out by M. Le Gallois, relating to the function of respiration, which it appears from what is said in my papers published in the *Philosophical Transactions* for 1833, 1834, and 1836, exercises so extensive an influence on all the other functions of the system, both in health and disease. It is true that the muscles employed in the act of respiration derive their nerves from the spinal

marrow, and that this organ is capable of its immediate functions, independently of the brain, among which the excitement of the muscles of respiration is one; but respiration is the most complicated of all our functions. In it many other functions conspire with this function of the spinal marrow. It appears from what is said in a paper published in the *Philosophical Transactions* for 1829, on the Functions of the Nervous System, and re-published in my treatise on the Nature of Sleep and Death, that among these functions is one of the sensorial power, which is destroyed by injuries of the medulla oblongata; and the failure of which as unavoidably interrupts the act of respiration, as the failure of the muscular or nervous powers on which the motions essential to that function depend. Thus it is that injury done to this part of the brain, however unimpaired the powers of the spinal marrow, immediately destroys respiration.

Such are the means by which all the contradictions which clogged our knowledge of the general laws of our frame were removed by the long-continued investigations in which I have been engaged. We are now prepared to review the practical inferences which necessarily flow from that knowledge, which we shall, in what remains to be said, find equally confirmed by the principles on which the functions of our bodies depend, the phenomena of the diseases in question, and the effects of our remedies.

It appears from the facts recapitulated in the paper which the Royal Society did me the honour of publishing in their *Transactions* for last year, that the powers of the nervous system, properly so called, perform but a subordinate part in the sensorial functions; they only afford the means of conveying to the sensorial organs the impressions which excite them, and to the muscles of voluntary motion the dictates of the will; while in the vital system they afford the leading power, that to which all its other powers are subordinate, yet it is in this system that the powers of the brain, spinal marrow, and nerves, have been overlooked. Can we be surprised, then, at finding that many diseases having their origin in the affections of these powers, should in their early stages be obscure; an evil increased in consequence

* See in the Report of the British Association for the Advancement of Science for 1833, a paper by Dr. Henry, of Manchester; and a Dissertation on the state of Medical Science from the termination of the 18th century to the present time, by Dr. Allison, Professor of the Institutes of Medicine in the University of Edinburgh, in the *Cyclopædia of Practical Medicine*, published in 1834.

of many of the vital organs being ill-supplied with nerves of sensation. Such, it will appear from facts I am about to state, is the source of a change which in many instances proceeds with few well-marked symptoms, till it at length produces effects that too often defy all our remedies.

One other point necessary to a clear understanding of the practical department still remains to be considered, before I conclude that part of the subject which relates to the laws of our frame.

As no serious attempt had been made to draw a correct line of distinction between the immediate effects of the sensorial and nervous powers, in like manner there had been no serious attempt to draw the line of distinction between the powers of which the animal body partakes, in common with inanimate nature, and those powers which are peculiar to itself, and we shall find that it is of no small consequence in our practical inferences, that it appears from the facts stated in the paper just referred to, that while the sensorial and muscular powers, and the powers of the living blood, are peculiar to the living animal; the nervous power, properly so called, the leading power in the vital functions, that power to which all their other powers, if we except the principle of vitality itself, are subservient, is in its general nature identical with one of those powers which operate in inanimate nature, it having been proved that all the functions of that power can be effected by voltaic electricity, made to operate under the same circumstances under which it operates*.

Such, indeed, has been the confusion which has prevailed on this part of the subject, that the nervous influence and vital principle have been confounded and regarded as one and the same, an error from which even Hunter is not exempt; although, of so different a nature are these powers, that the latter has no existence except in the living animal, while of the former it partakes in common with inanimate nature.

The vital principle belongs exclusively to no particular set of organs, but equally animates all living parts, the organs of the sensorial and muscular powers and the blood, as well as those

of the nervous power, properly so called. Is not the vital principle that which bestows on all living parts the properties which distinguish them from inanimate matter; while the nervous influence is an agent prepared only by a certain set of those parts, for the preparation of which both their own peculiar properties and their endowment with that principle are equally indispensable? How confused, then, have been our views of the animal economy, when such a physiologist as Hunter could have confounded with the general vivifying principle an agent, the existence of which in the living animal depends exclusively on one particular set of its organs, and is itself one of those powers of which the living animal partakes in common with inanimate nature! The vital principle might, even with more propriety, have been confounded with the muscular power, for wholly different as the properties of these powers are, the muscular power is at least one of those peculiar to the living animal.

The truth is, that the nature of the nervous influence having never been seriously made the subject of experiment, has been regarded as of so mysterious a nature, that it has been open to any fanciful properties which might be ascribed to it.

If there be any truth in the experiments publicly repeated both in London* and Paris†, and that on a great variety of animals, with the same results; the nervous influence, properly so called, that is in opposition to the powers of the sensorial organs, is, of all the powers of our frame, that which is best defined, and with which we are most familiar.

All its effects in the living animal, like those of electricity in the inanimate world, are chemical processes‡. This is strikingly the case with respect to the only function of the vital organs of the brain and spinal marrow, to which I have not already had occasion to refer. It is many years since Sir Ben-

* See the Philosophical Transactions, and the journals of the Royal Institution, both for the year 1822.

† De l'Influence du Système Nerveux sur la Digestion Stomacale; par MM. Breschet, D.M.P., Chef de Travaux Anatomiques de la Faculté de Médecine de Paris, etc.; H. Milne-Edwards, D.M.P.; et Vasseur, D.M.P. (Mémoire lu à la Société Philomatique, le 2d Août, 1824.) Extrait des Archives Générales de Médecine, Août 1823.

jamin Brodie* proved experimentally that the process which maintains animal temperature depends on the powers of the nervous system; and nearly as long since I found, by the same means, that the influence on which this process depends, is equally supplied by the brain and spinal marrow†: and that here, as in the other effects of the nervous influence, voltaic electricity is capable of its function. The temperature of living arterial blood was immediately raised several degrees by voltaic electricity, while no effect of this kind could be produced by it on living venous blood, which had undergone the action of the nervous influence.

In my next communication I shall give the first part of the practical inferences depending on the facts referred to in the present paper, and confirmed by the practical experience of thirty years. Many of the results I am about to lay before the reader were rather inferences from practical observations than the results of an application of the foregoing statements to the phenomena of disease; with many of which statements I was in the earlier parts of the above-mentioned period unacquainted. Thus actual practice and physiological experiment have mutually assisted each other in arriving at the practical results, and consequently have each tended to confirm the inferences from the other.

I am, sir,

Your obedient servant,

A. P. W. PHILIP.

SOME ACCOUNT
OF
THE SURGICAL CASES
WHICH WERE ADMITTED INTO
THE LIVERPOOL NORTHERN
HOSPITAL,

From the 1st Sept. 1836, to the 1st Sept. 1837.

To the Editor of the Medical Gazette.

SIR,

You have given insertion, in the MEDICAL GAZETTE, to two annual reports of

* Sir Benjamin Brodie's Papers in the Philosophical Transactions for 1813 and 1814.

† The first edition of my Experimental Inquiry into the Laws of the Vital Functions, published in 1817.

the surgical practice of the Liverpool Northern Hospital; will you oblige me by admitting the third annual list of the surgical cases which have been received into the hospital during the last year, viz. from the 1st of September, 1836, to the 1st of September, 1837?

I am only able to give a relation of some few of the most interesting cases which have come under my own care. The hospital now contains so many patients, that it would be difficult to take notes of the interesting cases of my colleagues as well as of my own; I must therefore leave to them the report of the cases which have come under their care. The following list, however, is of all the surgical cases which have been admitted into the hospital during the past year.—I am, sir,

Your obedient servant,

JOHN M. BANNER.

Liverpool, Oct. 10, 1837.

with effusion of blood. In one there was fracture of the parietal bone, with depression and laceration of the membranes; and in the fifth case there was a fracture extending across the skull, dividing it into hemispheres, and also rupture of the meningeal artery: in this case, symptoms of compression came on gradually. On examining the head after death, a large coagulum was found situated on the left side, between the skull and dura mater.

There were three cases of abscess *in perineo*; in two of these there had existed stricture of the urethra. The third arose from an injury.

There were four cases of stone in the bladder: three of them were operated on; the lateral operation was performed in two, and the recto-vesical operation in the third. In the fourth case, which occurred in a female, there had been a quantity of calcareous matter passed by the urethra for a very long time, and the patient continued to pass large quantities: it came away in thin broad pieces, which were rough, and perforated in many places. The symptoms which were present indicated disease in the kidney; consequently no means for the removal of the calculi in the bladder were resorted to.

The following are a few cases which I have selected from my note-book. The cases were taken down at the bedsides of the patients, and consequently are not drawn up in the best manner; they are, however, correct, and as such may be of some value.

CASE I. — Compound Dislocation of both Ankles—Comminuted Fracture of the Bones of the Feet—Amputation of both Legs—Death.

Thomas Thomas, æt. 41, was admitted into the hospital with compound dislocation of both ankles. He is of a full habit, and has generally had good health. He is a well-sinker. On the evening of the 3d of September, 1836, whilst descending in a bucket into a well 26 yards deep, the bucket turned over, and he was precipitated at least 17 yards. He was insensible for some time after the fall, and the first thing he remembers after it is, that two of his companions were standing by him in the well. He was conveyed as soon as possible to the hospital.

There was a large wound extending from the outer ankle of the right leg to

the centre of the sole of the foot. There was considerable displacement, the opening extended into the joint, and the bones of the foot were much comminuted.

There is a similar wound on the left foot, with this difference, that it extended more over the front of the foot; there was much displacement here, and considerable hæmorrhage from the wound, which extended into the joint, and there was comminuted fracture of the bones of the foot.

At the time of admission, the patient was faint, and it was some time before he rallied sufficiently to bear the operation of amputation, which had been determined on. The left leg was first removed (the one from which there was hæmorrhage). He bore the operation very badly, and was several hours before he rallied; in consequence of this, we determined to defer the second operation, which was not performed for sixteen hours after the first. This he bore much better than the first, and appeared to be doing well until the middle of the night (fourteen hours after the second amputation), when vomiting of bilious matter came on, which continued incessant; the pulse was quick and weak, and he complained of great languor. Mr. Blower, the house-surgeon, prescribed effervescing saline draughts, with small doses of opium, every three hours, and administered brandy often during the night.

5th. — The patient is restless; the countenance anxious; he has passed a sleepless night; the pulse is 130, and very weak; the tongue is dry; the vomiting is constant; the fluid ejected is much tinged with bile. The left stump was examined; it was quite cold, and the muscles were of a greenish colour, and on being touched did not convey any sensation to the patient.

R Pulv. Opii, gr. j.; Hyd. Submur. gr. ij. M. f. pulvis, 2d quaque horâ sumendus. Brandy to be given often. The stump to be fomented.

He gradually became weaker, and in the night of the 5th he died.

Examination of the Feet.—The left foot: the os calcis was found literally smashed, and the internal cuneiform bone was also much broken. A fracture also extended some distance into the astragalus; the capsular ligament was much lacerated.

The right foot: the os calcis was

much comminuted, as were also the cuboid and cuneiform bones. In this foot the astragalus had escaped, but the fibula was fractured, and there was considerable laceration of the ligaments.

Post-mortem Examination.—On opening the abdomen there was seen about two drachm of thick yellow fluid, resembling bile: this fluid was lodged between the gall-bladder and colon, to which it (the bladder) firmly adhered. On pressing the gall-bladder there did not appear any escape of bile into the abdominal cavity, nor could there be found any laceration of the liver; which was white, hard, and very adherent to the surrounding peritoneum. There were several ecchymosed spots on the intestines, and one (very large) on the stomach. The peritoneum over the right kidney was very dark, and beneath it was a considerable quantity of effused blood. The substance of the kidney appeared bruised; the inner surface of each os ileum was also ecchymosed. On examining the chest, there was an effusion of blood in each side of the thorax; the right side contained about eight ounces, the left four. The lungs were very dark; they crepitated, and floated well in water. There was a very dark place under the pleura, covering the fourth, fifth, and sixth ribs of the right side, near their junction with the vertebrae: these ribs were fractured, and a little above this part, at the root of the lungs, it was thought blood exuded through a very small opening; this, however, was very doubtful. The heart was large, and so adherent to the pericardium at every point, as to make their separation difficult. The inner surface of the aorta presented a bright florid appearance (such as is sometimes seen in cases of sudden death).

CASE II.—*Recto-Vesical Fistula—Calculus in the Prostate—Operation—Cure.*

John Green, æt. 11, was admitted into the hospital on the 8th of November, 1836. He is a healthy-looking boy, stout, and very short in stature. The grandmother, who accompanied the patient, gives the following statement:—"Rather more than three years ago, we first perceived that there was frequent desire to void the urine, and that while he was doing so he would frequently cry, as if in pain. We ascribed this to two or three accidents which had pre-

viously happened to him; for instance, on one occasion, whilst in the act of voiding his urine, a boy seized Green by the penis, and pulled it so unmercifully that inflammation and swelling came on, which continued a long time. About six weeks after this, he fell across a large piece of wood, and again produced inflammation and swelling of the penis. It was about five or six months after this that we first noticed the difficulty in making water; this appeared to increase upon him, and his rest was so much disturbed that we determined to obtain medical aid: for this purpose we took the patient to the neighbouring town (in Scotland), and had the opinion of two surgeons. They passed an instrument into the bladder, and felt a stone; they proposed that he should undergo an operation, which was objected to. The symptoms after this became gradually worse, and he often parted with blood in his urine, which now came away in drops. It was about a year after we first perceived the difficulty in voiding the urine, that he parted with a small calculus; it was nearly white, and about the size of a large pea, though much longer. After this stone came away he appeared much easier, and for ten or twelve months was comparatively free from pain, and the urine flowed much more freely. It was about a year ago that he became again very unwell; he was feverish, and constantly parting with drops of urine, mixed with blood and mucus. These symptoms continued for five or six weeks, when suddenly he felt relief: this arose from the urine coming away from the seat, and in three days after we first perceived this change, he had considerable difficulty in parting with his stool, and after straining much, he parted with a large stone. After parting with this stone he was easy, and, with the exception of the urine coming the wrong way, we should think there was not much the matter."

My friend, Dr. Mackenzie, had seen this patient in Scotland, and had obtained possession of the calculus which had been passed by the rectum. It is of the size of a large walnut, and weighs half an ounce (within twenty grains): it is composed principally of phosphate of lime.

A sound was passed into the bladder, which was found very much contracted. A calculus was felt, though very indis-

tinety; a roughness, as if the sound passed over the surface of a stone, was perceptible, but this could only be felt by drawing the instrument considerably out of the bladder, so that its convexity came in contact with the prostate gland.

On passing the finger far into the rectum, an opening sufficiently large to admit the point of it was felt; but the finger could not be got in contact with the bare instrument; it appeared to get into a cavity between the bladder and rectum, and, with the exception of one occasion, the bare sound could not be felt; in that instance, by endeavouring to strike the calculus with the sound, the instrument passed very much further than heretofore: this led me to pass my finger into the rectum, when I found the end of the sound protruding some distance into the bowel. The patient stated, that occasionally he parts with drops of urine through the urethra. I appointed a person to watch him, and orders were given to keep the urine.

The report was, that the patient had occasion to go to stool every ten or twelve minutes, and appeared to part with a small splash of water through the rectum; that he had not parted with any urine by the natural passage. The fluid he had parted with was about a pint in quantity, and was mixed with faecal matter. On questioning the patient, it appears that he never parts with formed stools, but always water by the rectum; and this has been the case ever since the bladder and rectum had ulcerated.

On passing a catheter into the bladder, on one occasion, a very small quantity of fluid came through it, which was faeculent, and had very much the appearance of that which comes through the rectum.

This patient remained in the hospital until May 1837, before a decisive opinion was formed as to what ought to be done. This arose, in a great measure, from the difficulty we had in feeling the stone. It was not until after many soundings that we were unanimous as to the existence of a calculus. Then another consideration was, the excellent health Green was then in; for with the exception of the inconvenience of having to part with the urine by the rectum, he was in good health and spirits.

On the 10th of May, however, he was attacked with febrile symptoms, and

parted with considerable quantities of mucus and blood by the rectum, and occasionally blood by the urethra. In consequence it was determined, as soon as these symptoms subsided, that an operation should be performed for the purpose of removing the stone, which we conceived was producing irritation by its presence.

On the 25th May the symptoms were much relieved, and the operation was performed as follows:—

Weiss's speculum ani was introduced into the rectum, after the patient had been secured as for the lateral operation; previous to which the straight staff was introduced into the bladder. An incision was made in a straight line, commencing from the prostate gland, and was continued to the point of the staff, when it was found that an incision of little more than an inch could be made, in consequence of the contracted state of the bladder. The straight staff was now withdrawn, and a curved one introduced, which enabled me to enlarge the incision about half an inch. On passing my finger through the opening into the bladder, I felt the stone firmly imbedded in the prostate gland. In consequence I enlarged the wound anteriorly, and with the aid of the forceps removed the stone. The calculus was firmly situated, and required slight exertion to disengage it. On introducing the finger into the wound after the stone was removed, the bed in which it had been contained felt rough, and there was evidently an incrustation of calcareous deposit attached to the cyst. The attachment was so firm, that an attempt to remove it would have been unjustifiable. The calculus weighs forty-eight grains, and its composition is the same as the stone which had been passed through the rectum.

June 1st.—The patient has not had an unfavourable symptom since the operation. The bowels have acted regularly; the whole of the urine has passed through the rectum; this morning a small quantity of the urine passed through the urethra.

4th.—He has passed his urine with greater freedom through the urethra; he is free from pain; the stools have contained more solid faecal matter.

7th.—He has had a slight febrile attack, with sore throat. By the use of leeches and saline purgatives he is better.

9th.—He has suffered a good deal from tenesmus, and is more feverish; complains of great thirst; yesterday he parted with two or three small pieces of calculus through the urethra; he continues to pass the greater part of the urine through the natural passage.

10th.—He has parted with a substance from the rectum; it has the appearance of a piece of thickened mucous membrane, covered with an earthy deposit; it is at least an inch and a half square. After passing this he became quite easy.

19th.—He continues to go on well; the principal part of the urine passes through the urethra; a large quantity yet passes through the rectum. The health is good.

27th.—He appears well in health, and states that all the urine passed through the urethra yesterday and today. Mr. Arnold, the house-surgeon, saw him pass urine this morning; it came away in a full and good stream.

July 1st.—He states this morning that he thought he had parted with a small quantity of urine by the rectum; but that he now has occasion only three or four times a day to part with his water, and once in the night, and that it always comes away with great ease, and in a full stream. I passed my finger into the rectum; the opening which I formerly felt from that gut towards the bladder was very much contracted, but was still there.

4th.—He was made an out-patient.

18th.—He attended at the hospital; he was in good health, and continues to pass the urine through the urethra in a good stream, and can retain it in the bladder a long time.

Oct. 7th.—Green called to see me today; he continues quite well; he now goes to school, and seldom requires to pass his urine between eight in the morning and twelve o'clock at noon; and seldom parts with it more frequently than three or four times in the day. The stools are solid, and he parts with them once, sometimes twice, a day.

May we not conclude, in this case, that the calculus which was situated in the prostate had prevented the flow of urine through the urethra? The opening in the bladder, caused by ulceration, could never be correctly made out; for notwithstanding on one occasion the sound passed from the bladder into the rectum, it was what I never could effect

again. There appeared to be a cavity between the bladder and rectum, for I could readily get my finger through the opening into the bowel, but could on no occasion feel the staff or sound which was in the bladder; there always appeared an intervening substance, like the side of the bladder. The opening in the bladder and the one into the rectum were certainly not opposite to each other. On one or two occasions, on passing my finger through the opening from the rectum, a quantity of fluid appeared to escape past the sides of my finger, but in no instance could I feel the bare sound in the cavity my finger entered; there always appeared to be the bladder between them. It was on the sixth day after the operation that the patient passed urine through the urethra; and although it was a very small quantity, yet it proves that there was a power left in the bladder to propel the urine through the natural passage, which would probably have taken place much earlier if the stone had not occupied the situation it did in the prostate. I conceive that the calculus in the prostate must have existed at the time the large stone passed from the bladder into the rectum, and might possibly have been in some measure a cause of the great irritation which the boy suffered in the commencement of his complaint.

CASE III.—*Fracture of the Coracoid Process of the Scapula.*

Alexander McCulloch, æt. 40, fell down a long flight of stairs, and alighted on his shoulder; he suffered very great pain, and was unable to move the arm. He went to a *bone-setter*, who told him that his shoulder was out of joint. He had considerable extension made by several men, and at last the bone-setter said "that he had put it in." Nevertheless the pain continued, and the inability to move the arm became greater. In consequence he made application for admission into the Northern Hospital.

Aug. 31st.—It is five days since the accident. The patient is a strong thick-set man, in full health. The shoulder and arm are considerably swelled, and he complains of numbness in the fingers. He suffers much on the arm being moved; the head of the humerus is in its proper position. A hard protuberance is felt in the axilla, which we ascertained

to be the coracoid process, and a small portion of the glenoid cavity of the scapula. The inflammatory symptoms which were present yielded under the antiphlogistic treatment. The parts were kept in as near a state of apposition as they could be placed in, and were continued so for several weeks. There was not any improvement; the pain continued great, the arm swelled, the numbness remained, and the process continued quite loose.

He was now ordered to use the arm gently, and passive motion was prescribed. By this treatment the parts appeared to adapt themselves to the case, and in two months he was able to use the arm in certain positions; he could never, however, raise it to a straight line. At the time he left the hospital the numbness had become much less, the swelling had nearly subsided, and he had a tolerable use in the arm. When I saw him in December, he was able to do the work of a warehouseman. The process continues moveable.

CASE IV. — Compound Fracture of the Skull, with Depression — Bone removed—Death.

John Fell, æt. 24, was admitted into the hospital on the 27th of September, 1836. He has always been in good health; he is a sailor, and has led a temperate life. It appears that a piece of iron, upwards of 9 lbs. in weight, fell a distance of seven yards on to his head while he was discharging a cargo from his ship. He was insensible at the time, but very soon recovered his recollection. He walked to the hospital from the dock, a considerable distance, supported by two men. The accident happened at noon, and he was admitted into the hospital soon afterwards; he was quite sensible at this time, and described accurately the manner in which the accident happened. There had been a considerable hæmorrhage, and the blood continued to flow freely; there is a wound $3\frac{1}{2}$ inches in extent over the left parietal bone; on making an examination, a fracture of this bone was felt extending in length $2\frac{1}{2}$ inches, and in breadth one inch; there were two pieces of bone driven in, and were resting on the dura mater. The hæmorrhage came from within the skull; there was a considerable quantity of brain under the scalp. It was an hour and a half after the man's admission before I visited him;

he was then quite sensible, the hæmorrhage had ceased, the two pieces of bone were quite loose; they were resting on the dura mater, and so covered with bruised brain, that they appeared driven into that organ; they were very readily removed; a coagulum was also removed from between the bone and dura mater; there was about half a teaspoonful of brain adhering to the loose portion of skull. In the operation of removing the bone there was some hæmorrhage from the meningeal artery: the patient was removed to bed.

8 P.M.—The patient is quiet and free from pain; the pulse is at 84, and rather weak; he has slept a little; cold lotion is applied to the head; he takes saline purgatives with tartarized antimony.

Sept. 29th.—He has had a good deal of sleep, at intervals, during the night; the face looks flushed, and he complains of slight pain in the head. The pulse is full, hard, and quick; the tongue is white and moist; the wound looks healthy.

V. S. ad xxx .

Taking away this quantity of blood caused syncope. The pain in the head was not relieved; the pupils are contracted.

1 P.M.—The pain in the head is very great; there is restlessness; he talks incoherently, and refuses to answer questions; the pulse is quick, but not full.

V. S. ad xxij .

when syncope again come on: eighteen leeches to be applied to the temples. Cold continued to the head. Turpentine enema to be administered every three or four hours, and a blister to be applied between the shoulders.

11 P.M.—The symptoms are aggravated; he is more delirious; the pupils are dilated, but act to the stimulus of light; the breathing is more difficult; he has constant throwing about of the limbs; the pulse has risen in strength, and is frequent; the bowels have been well relieved.

V. S. ad xxiv .

He fainted after this bleeding, and for a time appeared easier; the blister is beginning to rise; to continue the enema.

20th.—The breathing is more laborious; the pupils have ceased to act; the right pupil is much more dilated than the left; the pulse is quick and firm. Blood has been taken twice from the temporal arteries; after each bleed-

ing he fainted. The stertor became greater, and in the evening he died.

Post-mortem Examination.—On removing the skull cap, there was seen a laceration of the dura mater, two inches in length. The membranes of the brain were in a high state of inflammation; the whole upper surface of the left hemisphere was covered with coagulating lymph; there was a wound in the brain, under that, in the dura mater: the substance of the brain under the wound was very vascular, and might be said to be in a state of inflammation: this was not the case with the other parts of the brain. The right hemisphere was healthy, except a slight effusion of blood on the anterior lobe. The cerebellum was healthy.

CASE V.—Mortification of the Toes—Tetanus—Death.

Thomas Davies, æt. 31, was admitted on the 21st October, 1836, with mortification of the toes of both feet. He is a native of Africa, a sailor. He states, that a few days after his arrival here from Africa, he had been washing the deck of his vessel barefooted; the cold water had produced great pain and numbness in the feet. On his return to his lodgings in the evening, he sat near a large fire, the pain in the feet increased, and the next morning he observed blisters containing water. It is five weeks since this occurred; now there is complete mortification of the toes, and it is extending to the instep; the skin which is diseased is of a leaden colour, that which is healthy is perfectly black; the pulse is quick and feeble; the tongue white. A turpentine dressing to be applied to the feet, and over this poultices.

26th.—The line of separation is quite perfect on the top of the feet. The cuticle, which was loose, was removed from the soles; the commencement of the line of separation could be seen close to the toes.

30th.—This morning the patient complained he could not swallow; whenever he attempted to do so, he had a spasm in the muscles of deglutition. In fact, the tetanic symptoms became, each hour, more aggravated, and the following day he died.

Various medicines were tried, such as opium and tobacco; kreosote was tried in large doses; in the first instance five grains were given, rubbed down in

mucilage: this was increased to fifteen grains every hour: this was found to produce so much irritation, that it became necessary to administer small quantities of arrow-root: this treatment was persevered in until six p.m., during which time he had taken one drachm and a half, when, finding that it did not produce the slightest mitigation of the symptoms, tobacco enema were administered. The greatest relief was given by rubbing a strong ointment of belladonna in the neck and spine; this was only temporary, for the symptoms returned with greater violence, and on the third day of the attack he died.

On dissection nothing particular presented itself.

CASE VI.—Fracture of the Second Lumbar Vertebra—Death.

William Benson, ætat. 28, was admitted into the hospital, November 4th, 1836, with compound dislocation of the left ankle, fracture of the calcis and fibula, and fracture of the calcis of the right foot. There was also fracture of the second lumbar vertebra. He is a native of Ireland, and up to the period of the accident had been in good health. From his statement, it appears that he fell from the outer wall of the graving dock, a height of at least 10 yards; he alighted on his feet, and then fell backwards: he had great difficulty in getting on his feet, but found he could not stand. He then crept on his hands and knees a distance of more than half a mile to a brick-field; he was here discovered by a policeman, and brought to the hospital. He confessed after his admission that he had been stealing copper nails, and on seeing the police had dropped from the wall.

The accident occurred at one o'clock in the morning: in consequence of the extreme pain he suffered from the back, it was determined not to amputate the leg. He complains of great pain at the lower part of the abdomen and in the right hypochondrium. He had not any difficulty in parting with his urine and feces, and could move the lower extremities. He lived only three days after the accident.

On examination after death, we found the second lumbar vertebra completely fractured; the transverse processes were both broken off, and the body was broken from the spine; the ligaments were torn: and there was considerable

displacement of several portions of the bone: the cord, however, was uninjured, and although the bony canal was fractured across, yet the spinal cord was not in the least pressed upon. This accounts for the want of the usual symptoms attendant on such injuries: he had full power over the bladder and rectum to the last, and could move his lower limbs. Some time before death he had priapism.

CASE VII.—Ununited Fracture of the Femur—Operation—Cure.

John McCay was admitted into the hospital in September, with an ununited fracture of the femur. He is a ship carpenter; before the accident had always good health; he is 30 years of age. He states that he fell from a mast in Londonderry, and fractured the left femur; he was immediately conveyed to the Infirmary there; the bone protruded through the skin. The accident happened nine months before his admission into the Liverpool Northern Hospital; the usual means were had recourse to, (such as blistering, friction, and motion,) without any benefit; it was at last determined to cut down and remove the ends of the broken bone.

The patient was placed on his right side, and the left leg was flexed; an incision of 7 or 8 inches in length was made at the outer side of the thigh, and continued down to the bone; a second incision was made in the centre of the first, commencing at the front of the thigh and extending it to behind: this incision was four inches and a half long, and the integuments were dissected back, and the muscles cut through, until the bone was completely exposed: the lower fractured portion was more prominent than the upper one: there was a middle piece of about two inches and a half in length: this portion of bone was firmly united to the upper shaft, and lodged under the lower one, which caused it (the lower portion) to project; there was not any union of the lower shaft to this middle piece of bone or to the upper shaft. A strong piece of leather was passed under the lower shaft, and about an inch of the end was sawn off; there was very great difficulty in removing the end of the upper shaft and middle piece of bone; it was, however, at last accomplished by means of Hey's saw and the chisel. The edges of the bones were brought together. The

limb could not be much extended: this arose from the contracted state of the muscles: it was placed on the double-inclined plane. It is unnecessary to continue this case through the cure; suffice it to say, that in six weeks the wound had healed, and the bone was firmly united. He is now able to follow his work, as a ship carpenter; the leg is two inches shorter than the other, and he is obliged to walk with a stick and a high-heeled shoe. The ends of the bone which were removed were rounded and covered by a membrane which appeared to be a continuation of the periosteum. I was not able to obtain the nature of the treatment employed before his admission into the Liverpool Hospital. I thought of applying the seton in this case, but was of opinion that after a fracture had remained ununited so long, as was the case in this instance, that nothing but the operation of removing the fractured extremities could do any good.

CASE VIII.—Sloughing of portion of the Testicle—Cure.

Thomas Reece, æt. 30, was admitted into the Liverpool Northern Hospital, on the 19th of May, 1837, with disease of the testicle.

He states that about eight months since he perceived a swelling of the right testicle, which was not accompanied with much pain; occasionally it ached, and at times was quite free from pain; it was the aching which first drew his attention to the part, for while it was present it was accompanied with nausea. He has never taken any medicine, or used any application for this disease. About two weeks before his admission, the scrotum became very hard, and looked red; there was little or no pain at this time, and in a few days several small lumps formed in the scrotum and broke: this occurred in five places, and there was a slight watery discharge from them. He never had an attack of gonorrhœa or syphilis, nor does he recollect having hurt the testicle at any time. The patient now looks pallid and unhealthy; he is a sailor; he has lost flesh. The testicle is enlarged and very hard, and there is a rough uneven surface. The scrotum appears to be ulcerated through in four or five places, and at the bottom of each ulcer a white slough is perceptible. The probe can pass between the scrotum and the

sloughs for a considerable distance. A director was introduced into one of the openings, and an incision was carried through the others so as to connect them. The testicle could now be seen; it was uneven, and looked in a fungous state, and sloughy. A consultation was held on this case, when my friend and colleague, Mr. Wainwright, suggested that a mercurial course should be prescribed, and to dress the testicle with finely levigated red oxide of mercury. This plan was agreed to.

R Pil. Hydrarg. ʒi. ; Pulv. Opii, gr. iv.
M. et div. in pil. xij. capt. ij. mane
nocteqe quotidie.

28th.—He is under the influence of the mercury. The mouth is sore, and the face swelled; the slough is beginning to separate.

30th.—The slough has come away. That part of the testicle which remains looks healthy; it is, however, a very small portion of the organ: the mouth is very sore; the scrotum is much reduced.

Omit the pills.

July 1st.—He was dismissed cured. When the parts had quite healed very little of the testicle could be felt.

CASE IX.—*Fractured Skull, with depression—Operation—Cure.*

Edward Cogan, an Irish labourer, æt. 28, was admitted into the hospital on the 2d June, 1837, with fracture of the skull. It occurred in consequence of a blow from a block; he was standing on a stage to receive a heavy cask which had been hoisted out of a ship's hold; when the block was disengaged from the cask it came with great force against his head, and knocked him senseless. He remained in a state of insensibility for some time; on his recovering, he vomited several times, and parted with some blood from the mouth. On his admission, which was about an hour after the accident, he was in a state of stupor; the breathing was slow; the pulse slow and irregular, but full; the pupils are contracted; over the right parietal bone there is a considerable swelling, produced by effused blood, and there is a distinct feeling of fracture of the skull. There is not any wound of the scalp.

V. S. ad ʒxx. ; cold lotion to the head; saline purgatives.

June 3d.—He felt faint after the bleeding, and vomited. He has continued to vomit during the night.

The pulse this morning is 58, and very full; the pupils are dilated; the breathing slow, 18 inspirations in a minute; he answers questions on being roused, and will, indeed, hold a conversation: the bowels have acted; the tongue is furred.

Eighteen leeches to be applied to the temples; the cold to be continued to the head.

R Hydrarg. Submuriat. gr. x. statim.
sum.

Jan. 4th.—The stupor continues, and the breathing is laborious; the pulse is 55, and not full; the pupils are dilated, the left more than the right; the bowels have acted by the use of an enema of turpentine which had been administered every three or four hours. There is slight paralysis of the left arm and leg.

Hirudines xviii.; cold to the head; and the enema to be repeated.

In the evening 18 leeches were again applied to the head, in consequence of the patient complaining of pain, which subsided after their application.

5th.—The breathing is much better, and the pulse has risen to 63 beats in the minute; the stupor is still present, though much less; the tongue is furred, and brown in the centre; he is more restless; the paralysis is more complete; he has power over the bladder and rectum.

Apply 18 leeches to the head; continue the turpentine injections; continue the lotion to the head.

June 7th.—The stupor is nearly gone, and the breathing free; the pulse is at 78, and regular; he complains of a throbbing pain in the seat of injury; the pupils continue dilated; they act on the admission of light; the paralysis is much the same; the tongue furred and dry; the bowels have not acted since yesterday morning; he has had two injections, and 3 drops of castor oil.

8th.—The bowels have acted freely, and he is in every respect better.

10th.—He complains of more pain in the head; the pulse is at 80, and full, and there is a state of stupor about him which has not been present for two days.

Hirud. xij.

11th.—He is much relieved.—Pergat.

14th.—The swelling over the parietal bone looks red, and is painful to the touch: he has complained for some days of a throbbing pain in it; in other respects he is better. An opening was made through the scalp, and a large quantity of dark coagulated blood escaped with matter: the skull was felt denuded of the periosteum, and much depressed.

16th.—There is a dark-coloured offensive discharge from the opening in the scalp; he is much easier, and in other respects better; the paralysis of the arm is less.

26th.—He continued to do well until to-day: yesterday he had slight pain under the frontal sinuses, and felt languid. An aperient draught had been given, which relieved his bowels. In the night he had a severe rigor, and vomited twice; the tongue is brown, and dry in the centre; the pulse is frequent; he complains of great pain in the head, and there is more stupor about him. In consequence of these symptoms, a consultation was held, and it was determined to raise the depressed bone. A crucial incision was made of considerable extent, and the scalp dissected back. There was a very great depression of bone; the fracture extended in several directions: several large pieces of bone were raised and removed: on taking away a lower piece, about two drachms and a half of pus escaped. The greater part of the bone which was removed was quite bare, and looked unhealthy: the remaining portions were completely raised; the dura mater looked dark: the bone which was removed was of a triangular form; it measured at the base two inches, and on each side three inches. There was considerable hæmorrhage from the meningeal artery; the patient fainted, and the hæmorrhage ceased. The edges of the wound were brought together and a roller applied. At the time of the operation the paralysis of the leg was complete, and that of the arm considerable, though less than it had been. The strict antiphlogistic treatment was enjoined after the operation.

On the third day after the operation the paralysis of the arm had nearly disappeared, and that of the leg was much less; indeed, the difference was so great,

that before the operation he could not stand; on the third day after it he was able to walk, with assistance, into another ward to which he was removing for quietness.

August 21, a piece of bone came away through the wound.

September 4th.—The wound is quite healed, and the patient is perfectly recovered, being quite free from paralysis, and has all his faculties perfect. He was this day dismissed cured.

MR. MILLER ON EMBRYOLOGY.

To the Editor of the Medical Gazette.

SIR,

I THROW myself for publication on the liberality of your journal, which has been so often boasted as the vehicle of the communications of science.

In the year 1827 I attended Dr. Birkbeck's lectures on anatomy, at the Mechanics' Institution. I was then following the trade of a plasterer and modeller. Those lectures kindled in my bosom the love of anatomy: I determined to leave my trade and follow it. I offered my services as porter to the dissecting-rooms, but could not get an engagement. Mr. Green, of St. Thomas's, gave me employment in casting cases for his museum, for about twelve months. I then commenced forming a collection of my own. The subject I chose to investigate was embryology, and the connexion of the placenta to the uterus. I have examined the uteri of sixteen women who have died undelivered. In 1835 there was no preparation in London to prove the connexion of the uterus to the placenta, or the placenta to the uterus, except the preparation marked No. 3535 in the Hunterian Museum. The account of it was drawn up by Mr. Mayo, in the presence of Mr. Stanley and Mr. Owen; and all three concurred in thinking that this preparation established all the points of structure which are described in it. I would beg the attention of midwifery teachers to that preparation.

The paper on the Structure of the Uterus and Placenta, by Dr. Robert Lee, in the Philosophical Transactions,

drew my attention to another method of injecting, by making two injections to run at one time—the one in the hypogastric arteries and veins, and the other in the arteries of the funis, with different coloured injections, so that it might be seen where each terminated. I have succeeded in it. An artery as large as a crow-quill is seen to pass, filled with injection, from the uterus into the placenta. The large decidual vein round the margin of the placenta was filled with injection. In this vein there are three openings, as large as goose-quills, into the veins of the uterus. These three veins return the whole of the blood from the placenta into the uterus. In the greater number of uteri that I have examined, I have never seen more than four venous openings, and never less than three. There are also another set of vessels, called the decidual arteries and the decidual veins. The arteries go to the uterine layer of the decidua, and stop there; so do the veins; they form the short curling vessels of Hunter. Separate portions of this uterus were dissected by Mr. Green, Mr. North, and the late Dr. Hugh Ley, who saw the same appearances. I have the preparation now. I have also been successful in injecting other uteri.

In Magendie's *Physiology* (1829, p. 509), he says, "In animals, among the small vessels which go from the uterus to the placenta, there is not one which has the appearance of a vein." In my collection I have what shews the reverse—the veins and arteries are injected. In London there are twenty teachers of midwifery, and there is not one preparation to prove the connexion of the placenta with the uterus. The painter is known by his paintings, and the sculptor by his works. Why not the physiologist? Have they nothing to discover? What have the teachers in London done for the last ten years? Have they no preparation to produce that we never saw before? All is for money, and not science.

There ever will be in this, as in other callings, some few who, even in silence and solitude, and among the most disheartening difficulties, will travel the rugged up-hill path of science, urged by no other stimulus than the love of truth—seeking no other reward than that which results from the nobleness of their pur-

suits. Allow me to prove this:—Sir Astley Cooper can receive no more honours than he has got; behold him in his old age working every day; his preparations prove what he has done the last ten years. Go to Mr. Kiernan, and see his splendid collection; that shews what he has done the last ten years. Go to Mr. Langstaff's collection; that shews what he has done (his kindness to me I can never forget). Go to Mr. Salmon's collection; that shews what he has done. There is also Mr. King's (of Guy's) collection of the heart, which I have not seen. I grant that museums have been made in that period, but what discoveries are there in them? Allow a poor mechanic to tell what he has done.

I have dissected 127 human abortions, from two grains in weight to that of nine months, shewing the vesicula umbilicalis—shewing the omphalo-mesenteric arteries and veins injected—also, the germinal disk in the human ovum, I believe the only one known—the preparation at nine months in the series of the omphalo-mesenteric vessels; their existence at nine months is denied by Velpeau. I have a preparation shewing the first formation of the amnion and allantois in the human female; also in animals, shewing the amnion and allantois to be one membrane, so that the fluid in the one is the same as in the other.

I have dissected, in a series of animals, the vesicula umbilicalis, with its duct; also with the omphalo-mesenteric artery and vein. I have dissected four kangaroos, from two to four months, shewing that there is no urachus in that animal at that time. I have dissected and prepared also the whole series of the chick, at every second day of incubation. These dissections prove the following facts:—

1. The general causes of early abortion.
2. By looking at a placenta, if normal, it will shew where the fœtus was first formed.
3. How best to remove the placenta from the uterus, in order to prevent hæmorrhage.
4. The existence of a series of cells in the placenta, like a honeycomb.
5. The manner in which the first circulation takes place from the vesicula

umbilicalis, and the first blood-vessels formed in the embryo.

6. The second circulation. Do the vessels proceed from the *fœtus* to the placenta, or from the placenta to the *fœtus*?

7. In case of malformation without a bladder, the cause?

I could enumerate a few more, but shall soon publish them in my work. Taking them as a series of preparations, I am told they are unrivalled in Europe. In 1835 they were in part exhibited at St. George's, by Dr. Robert Lee; in his lectures at St. Bartholomew's, by the late Dr. Hugh Ley; and at the Westminster School of Medicine, by Mr. North; and since then by some other teachers. I think of placing them in some public institution, so that all persons may have access to them,—perhaps the British Museum.

Dr. Robert Lee introduced me to M. Coste, from Paris, a short time ago. This gentleman obtained a gold medal from the Institute of France for his researches on embryology. M. Serres is the reporter on the memoir to the Institute. I told M. Coste in the presence of Dr. R. Lee, that all he had written on the embryo of animals was wrong. Dr. Lee had seen my preparations in the sheep and the rabbit, with the vesicula umbilicalis between the amnion and chorion, twelve months ago, and might have confirmed me, but chose to be silent. I told him to call in three Frenchmen, and I three English—to put his book on the table, and I would put my preparations, and let those six report. Dr. Lee wished me to show him my preparations, and then to trust to the honour of M. Coste. This I refused. I at different times compared his plates with the preparations before Dr. Ferguson, of King's College, Dr. Ryan, Mr. Kiernan, Mr. Skey, and other gentlemen. All are convinced that he never dissected out the vesicula umbilicalis, but had figured the allantois for the vesicle. Mr. Owen, the Hunterian Professor, has fallen into the same error in his papers on the kangaroo, in the *Philosophical Transactions*, 1834, and *Loudon's Magazine of Natural History*, 1837; and is also wrong in saying a urachus exists in that animal. What could M. Coste, M. Serres, and Mr. Owen, be doing with their eyes?

This is the way that errors are propagated. Because they are great men, it is taken for granted that whatever they say is true, without being called upon to make preparations in proof, and the student never thinks it is necessary to investigate nature for himself. The plan I have adopted is the following:—I examine the uterus of animals at eight days after copulation, at fifteen, and at thirty days, or the calendar month. The cow goes nine calendar months, so does woman; and as I have found only four normal ova out of 127 human, I will see what, by analogy, I can make out from the cow. I am making a fetal preparation of each organ when formed, dating also the period when it is completed. There is one, an ovum of thirty days after copulation, in the mare, (in the Royal Veterinary Museum). I asked Mr. Sewell to allow me to examine it, but he denied me. I told him I was not to be beat, and would beg money to buy an ass to destroy it thirty days after copulation. I invited him and Mr. Colman to see my preparation, and see what I was doing. They have never come. Mr. Sewell asked me where I got my knowledge. I told him in an attic—for that was the best light for dissecting. What have they done at the Royal Veterinary College for the last ten years? I told Mr. Sewell that if he would teach physiology in the College, he must learn it from a mechanic. I beg that some one would intercede for me to examine that ovum, or procure for me a similar one: as I have got the ovum of the cow at thirty days, their comparison would be useful. If I was a great man I should not be denied; but I am poor—a pupil of a Mechanics' Institute, and not of a College. One high in the church told me to my face that I had drunk deep out of Dr. Birkbeck's cup—that the schoolmaster was getting too much knowledge. I pitied his ignorance. I know that those who have written on this subject do not like to be criticised by a mechanic; but by the truth I will stand or fall.

I will now give a description of the smallest human ovum in my series.

The first formation of the human ovum, with the germinal disk or spot. The ovum weighed four grains, and is five lines in diameter.

FIG. 1.—The Exterior of the Ovum.

- a. The chorion membrane.
- b. The floeculent chorion.
- c. The germinal disk, three lines in diameter.
- d. The puckering of the disk in the centre.

FIG. 2.—The Interior of the Ovum.

- a. The chorion membrane.
- b. The vesicula umbilicalis, two lines in diameter.
- c. The germ, three lines in length.
- d. The duct from the vesicle into the germ.
- e*. A vessel from the vesicula, in a direct line to the nearest part of the membrane at the head of the germ.
- e. A vessel from the vesicula to the membrane that forms the allantois of the germ, at the inferior part.
- f. The membrane that forms the amnion.
- g. The first formation of the urachus.
- h. The membrane that forms the allantois.

The membrane by which the amnion and allantois are formed is only one, as follows. It is an oval membrane, with the germ at the end of it, *i. e.* at *e**, where the shortest vessel proceeds from the vesicle to the membrane, so that the membrane becomes like the figure ∞ , or hour-glass; the large half is the allantois, and the turning in the centre becomes the urachus, *g*, and the fluid in the one is the same as the other. I have preparations showing the opening through the urachus (which can be seen with the naked eye) into the amnion.

As the allantois shoots to the membrane of the chorion, and the space being confined, it becomes depressed in the middle to suit the circle of of the ovum with the urachus along-side of the duct, from the vesicula umbilicalis to the germ. The interior of the ovum was filled with pellucid gelatine, which is always to be found in the normal ovum. I do not know the date of this ovum, as the woman met with an accident, and aborted in twelve hours.

By comparing this ovum with plate 1, fig. 4, in Velpeau's Embryology (which preparation is from Pockel), Velpeau doubts the accuracy of it, and asserts he (Pockel) must have made it with its long vessel from the vesicle to the allantois. I believe that part to be correct, although a great part of the preparation is abnormal. It is the vessel from the vesicula umbilicalis to that part of the membrane which forms the allantois.

In Dr. Barry's translation of Professor Wagner's *Inquiries concerning the Germinal Vessels*, in 1835, he states as follows:—"That in the human ovum there is present a germinal spot, appears to me probable. What may be its meaning? Does it stand in a certain relation to the embryo?" Also, in his translation of Dr. Valentine's *Development of the Human Ovum*, he states the following:—"It appears to be almost certain that the mammalia, before impregnation, possess no germinal disk, but merely a germinal vessel; the same is the case in the ovum of birds also, in the early stages of its development within the ovary."

I must confess that this subject still remains defective and dark: although the brightest names in the page of science have thought it worthy of their

researches, yet their reports contradict each other in many essential points.

The microscopic examinations of most men suit their own imaginations—a very unpardonable error. Papers written without preparations to prove the facts stated, should not be received in any Society. I grant that some appearances cannot always be preserved, but six men can always be found to prove the truth of these appearances.

There exists too much mystery in schools and colleges on this subject. There should be no mystical lore; knowledge is not mystical—it is only mystified to conceal something wrong. I have ova in my collection from six days and upwards after conception. Every man that has got eyes can see them as well as I can. I have got a diagram of the human ovum with the germinal disk, made by Mr. Perry; which every teacher of midwifery may use until he has one of his own.

I have given Mr. Perry permission to make diagrams of it; at the same time, no teacher shall use the diagram without having seen the preparation for himself.

Through the kindness of Dr. Ure and his son, Mr. Perry and myself had an opportunity of examining the ovum through his powerful lens.—I am, sir,

Your obedient servant,

JOHN MILLER,
Mechanic.

No. 3, Theobald's Road,
London, Nov. 6, 1837.

COMMON TOBACCO-PIPE BROKEN IN THE URETHRA.

To the Editor of the Medical Gazette.

SIR,

If you think the following case worthy a place in your valuable publication it is at your service.—I am, sir,

Your obedient servant,

THOMAS HAIGH MARTIN,
Surgeon.

Holmfurth, Yorkshire,
Oct. 28, 1837.

B. A. of Newcloses, in this neighbourhood, having been subject to occasional attacks of retention of urine for many years, was attacked with complete retention on the morning of the 19th June, 1828, for which I used the catheter. My father saw her on the 20th, prescribed a little medicine, and employed

the catheter sometimes once and sometimes twice a day, until the 2d August. But she being a pauper, and the overseers objecting to the expense of a medical man constantly attending, gave orders to the woman not to send to her medical attendant any more; from which time to the 15th September she employed a common tobacco-pipe three times a day; but, unfortunately, it being so brittle, she broke it in the urethra; and with the endeavours she made to extract it, pushed it into the bladder; from which time to the 27th April, 1829, it produced no inconvenience, she being provided by the overseer with a silver catheter immediately after the above accident, which she used two and three times a day. On the 27th April she was attacked with pains, which she described as similar to labour pains, but much more severe. My father was again requested to see her on the 28th, and found by examination *per vaginam* the pipe lodged in the cavity of the uterus, with one end protruding through the os uteri; but it was so strongly embraced by that viscus as to require the aid of a pair of dressing forceps to extract it, and so much force as to break the end of the pipe several times.

What I consider most remarkable is her never losing a single drop of urine but what passed through the catheter, which she continued to use three or four times daily up to the time of her death, which took place on the 30th November, 1834, after being confined to her bed entirely for three years or better, she having sunk at last from phthisis pulmonalis.

I was able to procure only a partial examination. The bladder was thicker than natural, but not the smallest particle of calcareous matter in it. On its left side, not far from the ureter, was a patch about the size of sixpence, which was much softer than any other part of the mucous membrane, and tore upon the slightest touch of the finger. I therefore concluded that to have been the place which had given passage to the pipe into the vagina, from whence it found its way into the uterus by the os uteri; as I should think it quite impossible it could have passed through the body of the uterus without leaving some sign of a cicatrix, which I was not able to find, although I brought away the uterus and bladder to examine them more leisurely.

The pipe is three inches in length, and was three inches round the middle part at the time it was extracted (from calcareous matter, which I believe to be the triple phosphate); but at present it measures only two inches and a half. It is now in my possession.

ON SCURVY.

From the Annual Report of

DR. MURRAY,

Principal Medical Officer at the Cape of Good Hope, for 1836.

Communicated by Sir James M. Grigor, Bart.

[Continued from p. 164.]

Report of Assistant-Surgeon Ford,—continued.

CASES VI. and VII. — The first patients with scurvy I admitted at Fort Willshire, were privates — Samuel Christie, æt. 28, and Thomas Atkinson, æt. 28, both of the 75th regiment, on the 12th of August, 1836, from Fort White; the disease being then of about three weeks' standing. They had had their usual rations, and half a gill of brandy daily, but had got no medicines. When admitted they were much exhausted, and unable to stand, from pain in the limbs and contraction of their knee-joints; the skin of their thighs and legs was extensively ecchymosed, and there was hardness and rigidity of the subjacent parts. Their general appearance denoted apathy and debility; countenance sallow and bloated. Christie suffered most from pain and straitness across the chest, and a catching in his breathing. Their gums were spongy and purple; teeth loose; breath offensive; urine scanty and high-coloured, and soon emitted a rank odour after being passed. Bowels regular; appetite good.

They slept better the night after their admission than before, probably from having comfortable beds. On the following morning they had a small dose of Epsom salts in bitter infusion, and their bowels were kept regular afterwards by occasionally drinking infusion of tamarinds. Their diet was as stated in the foregoing report, and after a few days indications of amendment were visible, and on the 28th of August, Christie left the hospital cured, but Atkinson remained eleven days longer, when he was also discharged cured.

CASE VIII. — Private James Henderson, 72d regt., æt. 34, was admitted Sept. 15th from Fort Cox, having evinced symptoms of the scorbutic diathesis since the middle of the preceding month. He had a soft, bloody, fungoid tumor, on the outside of the right leg, which was considered an indolent furunculus in the first instance, by the surgeon at Fort Cox; and an incision was made into it, and poultices applied, when a fungoid growth shot forth from it, known by the name of "*bullock's liver*," by seamen. The general symptoms were similar to those described in the two preceding cases, except that there was not so much debility. He had got nitrate of potass, sulphate of magnesia, and a daily allowance of diluted brandy, at Fort Cox, but without any appearance of advantage.

I employed the same general practice as before stated, and applied lint soaked in a saturated solution of chloride of lime to the fungoid ulcer; and on the 7th October (having been twenty-three days under treatment), he left the hospital perfectly recovered.

CASE IX. — Mathew Fyans, æt. 30, 75th regt., two months ill, was transferred to my hospital on the 6th Nov. The most urgent symptoms were constant pain, and frequent spasms in the region of the heart, especially during sleep, rendering respiration difficult and catching; great feebleness, particularly in the knees and calves of the legs; extensive ecchymosis and induration of the integuments of the legs, and pain in the ankles; gums not so spongy and livid as in the preceding cases; skin dry, *anserine*, and very itchy; countenance dejected, sallow, and puffy; pulse slow and feeble; bowels rather torpid; urine high coloured; appetite tolerably good. Former treatment unknown.

He had the same diet given as the other scorbutic cases; but had *two* gills of Cape wine daily, except during a few days that wine could not be procured, when he got one gill of brandy, with water, sugar, and fresh lemon juice, in lieu; 5ij. of Epsom salts, with tonic infusion, and tincture, were given every second or third morning, and a lotion of the solution of chloride of lime applied to the skin. He soon began to improve; but the pain in the heart, palpitation, and straitened breathing, still continued, when I handed him over

to Dr. Graham, 75th regt., on the 14th December, seven weeks after admission.

REMARKS.—It has occurred to me more than on e, that in this case moderate blood-letting would have relieved the cardiac symptoms, and raised the pulse, the depression of which I consider to depend on impeded and oppressed circulation through the lungs; yet, not being then aware of the introduction of this mode of treatment, and the success reported to attend its adoption, and having the opinion of physicians experienced in the treatment of scurvy before me, "that the disease by no means bears bleeding, even although the most acute pains upon the membranes, a high degree of fever, and dangerous hæmorrhages, would seem to indicate it," and that "the patient generally dies soon after the operation;" together with the consideration that this patient, being in an advanced stage of the disease, suffered from feebleness, and depression of energy and spirits, for which tonic treatment was required, I was deterred from using the lancet.

CASE X.—Alexander Liddle, æt. 36, 75th regt., received from the New Province on the 6th November, affected with enormous enlargement, intense ecchymosis, unyielding hardness, and much pain of the whole of the right lower extremity, and contraction of the knee. The gums, soft palate, velum palati, and uvula, were tumid, spongy, and livid; and purple-coloured fungi rose from the gums to a level with the edges of the teeth, interfering with mastication. He did not suffer much from pain of the chest, nor oppression of breathing, nor did he evince any tendency to faintness.

The same line of treatment was followed as in the preceding cases; and when I transferred him to Dr. Graham on the 14th December, he was hardly convalescent. He was soon after sent to Bathurst, and I have since seen him in the performance of his duties, wholly free from the disease.

CASE XI.—The worst case of scurvy that has fallen under my observation was that of private Huff Gavin, æt. 26, of the 75th regiment. This man first shewed symptoms of scorbutic affection at one of the out-posts in the New Province, about the latter end of August, and was treated in the 75th Regimental Hospital, at King William's Town.

In October he was removed with his company to Fort Cox, where he remained under treatment, chiefly of nitrate of potass, sulphate of magnesia, with brandy and water, until sent to Willshire, on the 8th of November.

At this period he was exceedingly exhausted, and fainted while being removed from the waggon to the ward. Countenance sallow, emaciated, and dejected; pulse small, frequent, and feeble; respiration short, quick, and oppressed (from pain in the chest); urine passed in small quantities, and high coloured; bowels rather torpid; appetite tolerably good, but has no desire for animal food; thighs and legs ecchymosed, stiff, and painful, with contraction of the knee-joints; pain and stiffness of the arms, and inability to use the hands; the pain of his loins almost prevent his moving in bed. The gums presented their usual state of sponginess. His debility was such, that even on the ninth day after his admission, while being carried on his mattress through the open air, from the old to the new hospital, he became nearly in a state of perfect syncope.

In the treatment, I deviated a little from my usual practice, but still it was conducted on the same principles, viz. that of exciting vascular action, restoring the healthy condition of the blood, and re-establishing the strength, by means of nutritious and corrective diet, and tonic, cordial, and saline remedies. During the first twelve days (having a distaste for meat) he had rice with milk and sugar, soup containing fresh vegetables, bread and milk, two gills of Port wine, and an orange, for his daily aliment; but afterwards he used the ordinary diet, with vinegar, two gills of Cape wine, and an orange, daily.

An aperient of Epsom salts, with infusion and tincture of gentian, when the bowels required assistance; 5 grains of carbonate of ammonia in 5ij. of camphor mixture, twice a day; friction of the extremities with soap liniment, and a gargle of solution of chloride of lime, comprised the medical means employed.

On the 21st November he was able to leave his bed; in two days more he moved about the ward; and after the 26th he enjoyed exercise in the open air daily. All the symptoms successively disappeared, and on the 9th December (just one month from the date

of his admission,) he left the hospital as a convalescent, merely labouring under some remaining debility.

In detailing the foregoing cases, I have candidly stated them to the extent of the information I acquired; I noted the symptoms of the disease, and the progress towards recovery, which I observed, to the best of my ability and without prejudice. I have also laid down the line of practice I followed, with all those affected with scurvy under my charge, and my reasons for its adoption; and from the favourable result in all who had been sufficiently long subjected to it, I conceive that my choice of it, and continuance in this mode of treatment (bearing in mind the class and state of the patients in whom it was employed,) are fully justified.

I am not prejudiced against, nor in favour of, any particular treatment; this, however, is the first opportunity I have had for the clinical investigation of scurvy; and it has been but partial, those only in advanced stages having fallen under my observation; but should I have an opportunity of investigating its nature at any future time, and of essaying the antiphlogistic treatment now recommended in its early stages, I shall not fail to avail myself of it, to give the practice a fair trial, and I shall feel happy if able to add my testimony to its beneficial effects.

P.S. I should decidedly say, that the men of the 75th regiment had not more, nay, not so much, hard work and fatigue in the New Province, in marching, exposure, felling wood, and hut and fort building, as the men of the 72d regiment; and as to "the huts left by our men," which I understand are now complained of, and brought forward among the causes of scurvy in the 75th regiment, there certainly were three or four of an expeditiously-built description among them, called "*Hartebeest huts*," which Colonel Smith caused to be completed; but all the rest were similar to those that were and are still usually erected at the different posts; and, indeed, at Fort Waterloo, where scurvy appeared very early, and prevailed extensively, I have learned that huts built there, under the superintendence of Lieut. Brown, 75th regiment, were the most comfortable in the New Province.

On having my memory refreshed, I

now perfectly recollect the "*anomalous neuralgic cases*," as they used to be called, in the 75th regimental hospital, at Cape Town, some years ago, which were certainly scorbutic. They occurred, I think, chiefly in men confined in the prison cells. I well remember their spongy gums, the great discoloration and swelling of their limbs, and the contraction and rigidity of their knee-joints, which Dr. Graham pointed out when I occasionally visited his wards; and which, by the by, he was treating *unsuccessfully* with tonic and stimulant remedies; among others, with large doses of carbonate of iron, as recommended in neuralgia. The 75th hospital was then seldom without one or more cases, so that the men of that corps even then evinced a tendency to this disease; while, in our regiment, I cannot call to mind a single instance, during the whole time we were in Cape Town, in which advanced symptoms of a scorbutic character shewed themselves, although I have a recollection of two or three being removed to hospital from the cells with spongy gums. If more of them were affected, it must have been in so slight a degree as not to render their admission into hospital necessary, as they never reported themselves.

IV. *Report of Staff Assistant-Surgeon Minto.*

February 1837.

During the year 1836 that I have been in charge of Fort Armstrong, in the Kat River Settlement, and the adjacent posts, it will be seen on a reference to my annual return, that the diseases of the detachments from the 27th regiment and Hottentot corps, which occupied them, have been of the most simple nature. The men were employed during the whole year in the construction of public works, and idleness and inactivity were guarded against. The European soldiers were quartered in a comfortable, well-ventilated, barrack-room, and were able very generally (but not always) to procure vegetables, and had very little patrol duty. They arrived from England in September 1835, mostly all young soldiers, with constitutions which have not been impaired by the immoderate use of Cape brandy, as we have had no canteens; than which I conceive there cannot be a greater evil at any out-post, whether in a mili-

tary, medical, or moral point of view : hence they enjoyed good health.

The Hottentot provisional troops erected for themselves such huts as they usually dwell in, which secured them against the inclemency of the weather ; and their food and clothing were infinitely better than that they had been accustomed to.

These circumstances may perhaps afford a sufficient reason why the men under my charge have not been at all affected with scurvy, which prevailed so much among the men of the 75th regiment, in the Caffer Province of Adelaide.

In order to ascertain if scurvy was known to the natives of this part of the country, I set an investigation on foot throughout the Hottentots of this settlement ; and found that none of them had ever seen or heard of any disease approximating to it among them ; and further, from all I could learn, it seems to be one to which none of the coloured tribes of this part of Africa are subject ; at least so far as the travels of the oldest people here have extended.

In regard to prevention, I would say, that when there are no public works going forward at military out-posts, I think that much good may be done, and much evil prevented, by introducing active exercises and exhilarating amusements among the men. None but those who have lived at a small military out-post can conceive the state of apathy into which soldiers generally get when unoccupied.

[To be continued.]

SALTS OF LEAD IN CHOLERA.

To the Editor of the Medical Gazette.

SIR,

IN one of your former numbers I observed some remarks of Dr. Graves', relative to the use of acetate of lead in cholera, in which disease it was found by him eminently successful. I have, however, to observe, that I gave the acetate of lead a very extensive trial in the cholera hospital of Bethnal Green, and found it equally inert with most other remedies. I would also observe, that the acetate is not the best formula ; for the evacuations from the stomach and bowels are usually *alkaline*, and

consequently the oxide will be precipitated. Free carbonic acid will also precipitate carbonate of lead from the acetate, which may, however, be obviated by the addition of a sufficient quantity of free acetic acid.

The late Sir D. Barry requested me, as physician to the Bethnal Green district, and the cholera hospital there established, to try the salt of lead. His observations were, "that he considered the disease a *serous hæmorrhagy* (flux ?) from the bowels, and that acetate of lead, therefore, seemed to be the most appropriate astringent." But although administered in large doses combined with opium, it proved inert, and frequently seemed to aggravate the cramps. It is true that the diarrhoea was occasionally suppressed during its use ; but I much question if this were not as much owing to kino or catechu, which upon such occasions were administered with it. Finding the different acetates so inert, I still determined to give lead an additional chance, and therefore exhibited the *nitrate* of lead, as a less *decomposable* salt ; but I still found this preparation, if not inert, at least of but equivocal powers ; administered, too, under every variety of form and mode. It was most successful when aided by kino or catechu.

Such is the result of my experience. But although I feel bound to make this statement, yet I am willing to believe that there may be something of change perhaps since, in the nature of the disease, and that possibly cases now may prove to be more under the influence of the metallic preparations, of the varieties of which, the nitrate, for obvious reasons, must be the preferable ; and therefore I agree with you, sir, that should occasionally, unfortunately occur, practitioners should give due attention to Dr. Graves' suggestions.

But I must say that, upon reviewing the accounts, I do not find a less mortality than has been published in the tables appended to my pamphlet on Cholera ; and in which the practice adopted will be found detailed at sufficient length.—I remain, sir,

Your obedient servant,

R. VENABLES.

17, Ely Place,

publicum sit, dicendi periculum non recuso.*”

CICERO.

DISPENSARIES IN LONDON.

DURING the discussions upon the Reform Bill, the case was often put of an intelligent foreigner being the spectator of our political proceedings; and it was asked by either party, alternately, what would such an educated stranger say if he saw the eccentricities of our opponents? What would he say to an election carried on by Sir Mark Wood's servants at Gatton, or to a torrent of cabbage-stalks on the hustings at Covent-Garden? Now let us suppose the “intelligent foreigner” to be a physician, and therefore sympathizing with the more confined circle of our medical interests. Let us imagine him to take up a newspaper, and find an advertisement for a dispensary physician, who must, as usual, be a member of the Royal College, and possess satisfactory testimonials. He might learn, on farther inquiry, that it was a common thing to spend a deal of time, and some money, in canvassing for such a situation; and that there have been occasions when candidates, stimulated by the desire of high preferment, have laid down Bank notes against each other—that is, have paid in subscriptions in the names of imaginary governors, and have thus gained their election at the Grub-street Dispensary, in the same way that they might their election as M. P. at Leicester or Liverpool. The intelligent but not naturalized foreigner, knowing that a professed philanthropist cannot always be had for advertising, and that a *nation boutiquière* must contain many cautious men who are unwilling to exchange solid sovereigns

for empty titles, necessarily supposes that the office gained with much expense, and held with infinite trouble, is very lucrative. What would be his surprise on hearing that the place is almost always a gratuitous one? Or, to drop the foreigner, how significant are the quiet inquiries of sensible people, when they see their medical friends canvassing for a place of nothing per annum! They naturally want to know why the candidate is so eager to obtain zero. Because it leads to practice, replies the abashed canvasser. But then, rejoins the friendly doubter, we do not see why this snatching at a shadow should be more necessary in physic than in the other learned professions. In the law, for instance, we sometimes hear of a cause being pleaded gratis; legal opinions, like medical advice, are no doubt occasionally given without fee to the needy client; but the barrister who should set up a legal dispensary where he doled forth his advice to all comers without a fee, with the avowed intention of getting into practice, would, we more than suspect, be speedily sent to Coventry by his brethren. It may be replied, of course, that medical advice is more frequently necessary than legal counsel to the indigent, and should therefore be provided for them gratis at the expense of the community. This we readily grant—at the expense of the community; but that this be done, the medical officers should be well paid, for at present the charitable bestowal is chiefly at their expense.

In the church — But here the newspapers of the day contain something quite *à propos* to our subject, and we must begin by detailing it. It appears that in the opinion of many friends of the church of England, there is a deficiency of curates in populous places, and an attempt is at present being made to supply the want. Now if the

competition were equal, as some erroneously suppose it to be, in all the learned professions—if divinity were reduced to the same straits as physic, the method of obtaining one hundred or five hundred additional curates would be obvious enough; it would suggest itself, without our mentioning it, to every medical man. Suppose an additional curate to be wanted in the parish of St. Giles's. The vestry would advertise on the 1st of the month, that candidates for the appointment, who must be graduates of Oxford or Cambridge, were to send in their testimonials on or before the 15th, and that the election would take place on the 29th; adding, that particulars of the duty required (among others, of course, that of being content with a stipend of 0) might be learned at the Vestry-Clerk's office. Testimonials would accordingly arrive in shoals, bearing witness to the long experience, excellent character, and unwearied zeal, of the respective candidates, and stating, that if there was any office for which they were more fit than another, it was that of assistant-curate to the parish of St. Giles'. Many also would possess certificates, showing, that, in addition to the required degree of B.A., they had taken those of M.A. and B.D. We need not describe to medical readers the advertising and letter-writing, and testimonial-soliciting; nor the going over the ground, as the phrase is, twice at least, by the candidate and his friends, which would necessarily occur. Yet more; we should hear the congratulations of the friends of the fortunate candidate, and their assurances that he might consider himself as within ten years of something comfortable—of a benefice of 80*l.* a year at the very least—if he behaved with zeal and discretion; at any rate, that he might be quite sure, if he was getting nothing else, that he was “getting known.”

Such things might easily be; but as

yet they are not. The friends of the church, in the present instance, are not giving votes and certificates, but solid cash; and the long lists of large subscriptions for providing additional curates, would seem to show that it is thought that, in one profession at least, hard work deserves something better than empty praise.

In the case of the dispensaries, it must be confessed that if the medical officers are somewhat slow in discerning certain unpalatable truths before their election, they find them out quickly enough afterwards; a few months are usually sufficient to teach that no pay is attended by another stern negative—no increase of practice; to which are added the uncomfortable positives—much work, and plenty of squabbling. The consequence is, that places are thrown up with wonderful readiness: service is found to be no inheritance. At a worn-out dispensary (a *ci-devant* respectable one), we have known four vacancies to occur, in the post of physician, in less than three years.

This dispensary, like others of the old school, once enjoyed the services of stipendiary officers; but when its income declined, and it became necessary to curtail its expenditure, the most obvious way of doing so was to cut off their salaries; for as druggists, leech-venders, messengers, and the like, insist upon being paid, and as this is a matter of indifference to physicians and surgeons, the natural conclusion was, stop these useless salaries, and thereby add so many hundreds to the income, and consequently to the efficiency, of the dispensary.

Let us be allowed to illustrate this very natural argument by an anecdote. Apicius Smith, Esq. kept one of the best tables in London. As almost every one knows, at least theoretically, what a good table is, we will not enter into details, nor speak of the *patés de Périgord*, the *rognons au vin de Champagne*,

or the curious *Johannisberg*, to be found upon his over-hospitable board; but we will just mention that his cook had a salary, not at all resembling the wages of a dispensary doctor, but a very comfortable thing indeed. Fortune, however, at last frowned upon Apicius Smith; Spanish bonds and South American mines rapidly reduced his capital, and it became necessary to retrench. One of the easiest retrenchments to make seemed to be in the stipends of the officers of the kitchen: indeed, after a few changes, he found it ultimately practicable to obtain their services gratuitously; for many thought that the fame of having served so great a gastronome would be a certificate of competency. But the hero of our tale was not slow to discover that he had better have economized at his table than in his kitchen; that what was gratuitously done was ill done; and that he was virtually, though unintentionally, keeping a school for cooks, as most of his new officers of the mouth were satisfied with a little improvement, and six or eight months' work without pay.

This is the short-sighted principle on which almost all dispensaries are now conducted—or miscondacted; but we confess our astonishment that so respectable an institution as the St. Mary-le-Bone Dispensary should have lately fallen into the common error, and passed a law that “no physician or surgeon hereafter appointed will receive any salary or gratuity from the funds of this charity.”

Any one who is acquainted with the subject, and has the interest of the poor really at heart, will allow that all that is done in London by twenty or thirty ill-conducted dispensaries, might be infinitely better done by six or eight good ones, with ample funds, and well-paid medical officers, devoting the greater part of their time to the institutions. The saving in house-rent,

taxes, and other items, which would be effected by such a coalition, would at least balance the increased expense caused by the salaries.

One of the most obvious improvements which would necessarily follow a reform of this kind, would be in the arrangement of the houses intended to be used as dispensaries. At present they are commonly unfit, architecturally, for the use to which they are put. Then it would be absolutely requisite that the hours of attendance should be considerably extended. How inconvenient it would be for the public if a medical practitioner were to be found at home for one hour only every day, or if a government office were to be open only from twelve to one. It continually happens, too, that the patients are thrown out by the accidental punctuality of the medical officer. Suppose that, as usually happens, he is habitually half an hour later than his printed hour; to-day he comes to the minute; his tail, or late patients, presuming upon his regular lack of punctuality, miss him altogether. But it is often said, all the patients ought to be there at the hour printed on the letters; if so, many will have to wait an hour, and some much more,—a serious loss for a patient who, though labouring under a chronic disease, still continues to work; while it is besides an injury to the health of many.

As, in consequence of such a coalition, the remaining institutions would be of far greater importance, we should expect to see persons of more weight in society, both lay and medical, interest themselves in their interior economy. It is almost needless to particularise the reforms to which this valuable superintendence must lead. The quality of the drugs would be improved, when the druggists were informed, quite in earnest, that trash and *pulveres redacti* must be sent elsewhere, and not to persons competent to judge of them.

The same cause would quite alter the system of dispensing medicines. No more substitution of gentian for cascarrilla—no more verbal directions—no more lumping of six powders into one*. We must conclude with the painful reflection, that most of these charitable institutions in London, as at present managed, are in bad odour among the poor, and produce more discontent than gratitude.

As to their supposed effects upon the fortunes of the physicians and surgeons connected with them, the truth must come out in this age of expositions, confessions, and *éclaircissements* of all kinds: the bubble must soon burst, and we shall not be sorry to see it do so.

LECTURES ON FORENSIC MEDICINE.

WHEN the course on Forensic Medicine, the publication of which we commenced last year, was interrupted by the lamented death of Dr. Cummin, we promised to complete the lectures on this subject from another source, "as soon as we could do so in a manner consistent with the very high character of those already given." We are happy in now having the prospect of doing this, and we this week insert the first of a set of lectures, which, by a remarkable coincidence, are delivered at the same school as the course a portion of which we published. We shall confine ourselves as nearly as pos-

sible to the subjects not treated of by Dr. Cummin, and have reason to believe that the pledge to our readers above quoted will be now amply redeemed by the lectures of Dr. Southwood Smith.

INDECENT MODE OF ADVERTISING.

A SURGEON in the city, who has contrived to establish a dispensary in Charterhouse Square, is annoying all the inhabitants of that district by the exposure of a board in the front of the house, on which is inscribed, in large letters, "Infirmary for Diseases of the Rectum." Notwithstanding numerous remonstrances, both friendly and hostile, he refuses to remove the nuisance; and, we understand, even threatens to insert words which shall make it more offensive. So indecent a mode of attracting attention we never before heard of from any one who occupied the place of a regular practitioner.

REFUSAL OF A CERTIFICATE TO A PUPIL.

WE are informed of the following case having occurred at Guy's Hospital:—A pupil who on the occasion of the late disputes between that hospital and St. Thomas's had been subpoenaed to give evidence in favour of the latter, on applying for his certificates was refused them by two of the lecturers, and referred by them to the treasurer. This gentleman also declined complying with his request, but returned him his money.

The case, as we are informed, is aggravated by the general opinion, which is in favour of the pupil's having been a diligent attendant on the lectures, and on all his studies, and by the circumstance of his being obliged to give evidence against his own school having been the consequence of an expression which he unintentionally made use of, and which seemed to make it probable that the "row" was premeditated by the pupils of Guy's Hospital.

* We once knew of a singular curing by mistake, which took place in consequence of the conglomeration of half a dozen powders. A practitioner had prescribed some tatar emetic for a woman labouring under a fit of indigestion. From whatever cause, the medicine did not operate, and the patient went to a Dispensary. Leeches were ordered to be applied to the right side, and a mass of Dover's powder was given her, to be taken at intervals, in small doses. The directions being given *dispensarially*—that is, in words alone—and being misunderstood or forgotten, the woman took the powder so freely as to produce a state of narcotism, with occasional fits of vomiting. The patient was extremely indignant, but was very much benefited by the vomiting—a vomiting not produced when intended, but which followed one of the most unusual of 11. emetics, the pulv. ipecac. comp.

If the story be untrue, the officers of Guy's ought immediately to contradict it, and we shall be happy to give publicity to such denial; but if otherwise, and if this gentleman can prove his attendance at the lectures of which his certificates are now refused, we should recommend him to have recourse to legal proceedings to save himself from the loss of twelve months or more of study.

CLINICAL LECTURE

ON

VARICOSE VEINS AND ULCERS OF THE LEGS;

Delivered at St. George's Hospital, Oct. 24, 1837,

By SIR B. C. BRODIE, BART.

Varicose Veins continued — Necessity of Rest — Bleeding — Various Applications — Varicose Ulcers — Different kinds of Plaster; mode of applying them — Application of Ligatures — Cutting the Vein across — Sir Benjamin's method of dividing the smaller Veins — M. Velpéau's plan.

I HAD not an opportunity of completing, in the last lecture, my observations on varicose veins of the leg. I explained to you the pathology, the symptoms, and the consequences of the disease; and I began to speak of the treatment which it requires: I shall continue the latter subject in the present lecture.

In those cases in which, from long neglect of varicose veins, the skin of the leg becomes red and irritable, you will be able to render the patient no service so long as he is going about, standing and walking as usual. The first thing to be done is, to confine him to his bed, or at all events to a sofa; but the safest method is to confine him to his bed, and the horizontal posture, so that the blood may not have to rise up in the leg against its own gravity. In many cases nothing more is necessary than this; but, in some instances, this will afford but very slow relief, and in all cases you may hasten the patient's recovery by adopting other methods in addition: I have frequently, in these cases, bled the patient in the vena saphena major, in the lower part of the thigh, near the inner condyle; and it is astonishing what relief that gives. It is not worth while to adopt this practice in all cases, but where you find the patient suffering more than usual from the inflamed state of the skin you may very properly have recourse to it.

Bleeding in the vena saphena major is performed very easily in persons who are not very fat: place a bandage round the lower part of the thigh, let the patient put his leg into a pail of warm water, and what with the warm water below and the bandage above, the vena saphena swells; you then open it with a lancet, and take away any quantity of blood you please. But, in a very fat person, bleeding from the vena saphena is not very easy to be accomplished, and as a substitute for it you may apply leeches to the inside of the thigh, or you may apply them in this situation in other cases where you do not think that actual bleeding in the vena saphena is required. And here I must call to your recollection what I said respecting the application of leeches, under these circumstances, in my last lecture. Never apply leeches to the inflamed part, but always at some distance above it. If the whole skin of the leg be inflamed, then apply them on the inside of the thigh; if the leg be inflamed in the lower part and not in the upper, then apply them in the leg, but above the inflammation. Besides the application of leeches, you may, in the first instance, apply a rag, wetted with cold spirituous or saturnine lotion. When the inflammation of the skin has subsided, you may begin the use of bandages in the way which I described in the last lecture.

In some cases, as I formerly told you, the skin is not only inflamed, but more or less excoriated, the cuticle being abraded to a greater or less extent, while the surface of the cutis secretes an ichorous fluid. Here, also, you may take away blood from the vena saphena major, or from the inside of the thigh by leeches, and the patient will also derive benefit in these cases from the application of a saturnine lotion, though, for the most part, some mild cerate answers the purpose better. The zinc ointment or calamine cerate answers very well; but we use, in the hospital, a preparation known with us by the name of compound chalk ointment, which is much preferable. It is, if I am not mistaken, now introduced into the Pharmacopœia under the name of Ung. plumbi compositum. It is an excellent application in these and other cases where the surface of the cutis is deprived of the cuticle. This ointment was invented by Dr. Kirkland, a celebrated practitioner many years ago in Leicestershire, and I believe it was commonly known under the name of Kirkland's neutral cerate. It is composed of diachylon plaster, olive oil, chalk, and distilled vinegar. How it should have ever entered into any man's head to make such a composition as this I do not know, but the composition having been invented I must say it is a very useful one. The

ointment should be spread on linen rag, and applied in stripes round the leg, each stripe over-lapping the one below. In some cases, in addition to the use of chalk ointment, you will find advantage from washing the surface with a weak solution of nitrate of silver, in the proportion of two or three grains to an ounce of rose water. A strong solution would here be improper, but a weak solution is very useful.

I told you that in some cases there was œdema, a swelling of the leg and foot, in consequence of the inflammation of the cellular membrane, causing it to be infiltrated with coagulated lymph and serum. The treatment that is required under these circumstances is very nearly the same as that which is necessary where there is the inflammation of which I have just spoken. The patient should be kept in the horizontal posture; blood may be taken either from the vena saphena major, or by leeches from the thigh, and generally you will find the latter quite sufficient. You may apply a cold lotion in the first instance, but very soon, in these cases, you should begin to apply a bandage, such as will give an uniform support to the leg from the toes to the knee.

In cases of varicose ulcers of the leg, if you find that the patient has neglected himself, that the ulcer is in a state of inflammation, foul and painful, as it often is, and the surrounding skin being in a state of inflammation also, you must keep the patient in bed, and treat him as if the leg were inflamed without the existence of the ulcer. But as soon as the inflammation of the ulcer and the surrounding parts has been relieved, you may begin the application of pressure. The pressure of a common roller will do a great deal of good, and formerly nothing else was recommended. But we find, now, that in cases of varicose ulcer, as in cases of indolent ulcer of the leg, you may very much assist the common roller by the addition of other means. One very good way of making pressure on a varicose ulcer is to interpose between it and the bandage a piece of sheet lead, such as is used in anatomical museums for covering preparations. The lead should be made quite smooth, and larger than the ulcer, extending some way beyond its margin. This makes a very uniform pressure, and really does very well. But for the most part we are in the habit of using pressure by means of plaster applied in a circular manner round the limb. It is common to employ stripes of linen spread with soap or adhesive plaster, but I own that I very much prefer diachylon plaster, for both soap plaster and adhesive plaster will frequently irritate the skin, and bring on inflammation and pustules,

but diachylon plaster scarcely ever produces this effect.

You have an opportunity of seeing stripes of diachylon plaster applied every day, and over and over again every day, in the wards of the hospital; and, therefore, it might seem almost superfluous for me to make any observations on the mode of applying them. But I find that new dressers very seldom apply them in the manner that I believe to be proper, and therefore I shall offer to you some observations on that subject.

In the first place the stripes should be applied round the limb, the two ends crossing each other in front, the application beginning below the ulcer, and extending some way above it. Each of the stripes ought to overlap the one below by one half of its diameter. Thus every part has a double piece of plaster over it, and you secure more equal pressure than you could otherwise obtain. It is of great consequence that the plaster should be tight enough to give comfortable support to the limb, and at the same time not so tight as to make the limb swell below; for if it does produce this effect, it is very likely that it will bring on a sloughing of the sore. The plasters ought to make uniform pressure — that is, the pressure should be equal throughout; or if there be any difference in the degree of pressure, it ought to be greater below than above. If you do not attend to this point, the plaster above operates as a tight garter, and makes the parts below swell.

When you apply the plaster, it should always be with the heel raised, the patient lying flat on his back, so that the vessels of the leg may be emptied of their blood. The same plan should be adopted when the plaster is taken off. If the leg be hanging down at the time the plaster is applied, the veins are full of blood, and the plaster becomes too loose as soon as the patient puts his leg up.

The plaster, if there be much discharge, should be changed daily; but as the discharge becomes less in quantity, it may be changed every other day, or once in three days, and in some cases it may be left on even longer than that.

Frequently, in cases of varicose ulcer, you find the veins on each side of the leg just above the heel, and behind the ankles, formed into a varicose cluster. A bandage applied in the common manner does not, sufficiently support these veins. The ulcer may be above, and you may cover it with a bandage; but if there be such veins, as I have mentioned, below, you must not, for obvious reasons, leave them uncovered.

In order to support these veins, some stripes of plaster should be applied round the lower part of the heel, ex-

tending upwards in a longitudinal direction on each side of the leg. Let these be held firmly on while you apply the circular stripes over them, in order to keep them in their place. In this case also, in the application of the bandage, you ought to pursue the same course: a longitudinal bandage, extending under the heel and up each side of the leg, should be applied first, and this covered by a circular bandage afterwards. These may appear matters of little importance, but a great deal of your success in practice will depend on attention to such minutiae. It is not enough to understand the case, to make a good diagnosis, and to know what remedies are to be employed; you should also take pains to apply these remedies in the best possible manner, otherwise they may fail in producing their effect. In some cases of varicose ulcer you will promote the healing of the ulcer by touching it every other day with a strong solution of nitrate of silver in water, beginning with five or six grains to an ounce, and increasing the strength gradually. But I do not advise you as a general rule to put any application in the way of dressing under the plaster. I find a new dresser frequently interposing a piece of lint, with or without simple ointment, between the plaster and the sore. It is a very injurious practice; it keeps the sore slopped with its own discharge; it prevents the plaster from making that uniform and regular pressure which is required. When the sore has been healed, the patient should continue to wear the plaster for *some time* afterwards, otherwise the cicatrix will give way, and for the same reason he should *ever* afterwards wear the bandage.

Other methods of treating patients labouring under varicose veins have been proposed by surgeons in former times, and also of late years. They have proposed to relieve or cure the disease by performing operations upon the affected veins. I need not carry you back to the propositions of Celsus on this subject, nor even to those of Heister. I shall only speak to you of methods that have been suggested within the last 30 or 40 years.

Sir Everard Home recommended the application of a ligature, where the veins of the leg were varicose, to the vena saphena major. He performed this operation in a great number of cases, and in a few cases he applied it to the vena saphena minor. When I was a student, nothing was more common than to see a patient with varicose veins standing on a table, and leaning over the back of a chair, to have this operation performed. The skin was divided; a silver needle, armed with a ligature, was passed under the

vein, and the vein was tied. In many instances, at first, no ill consequences ensued; but by and by a private patient of Sir Everard Home became affected with venous inflammation, and died. The same thing then occurred in another patient. When I was house-surgeon here, there were two women on whom the operation was performed, in each of whom venous inflammation, attended by typhoid symptoms, supervened. Fortunately they did not die, but they had a very narrow escape. The operation was performed by other surgeons, and in their hands also it was found that every now and then venous inflammation was brought on, which ended fatally. The operation was then generally abandoned. Mr. Abernethy remarked,—“I dare say it is only the ligature that brings on the inflammation. You divide veins when you amputate, and they do not become inflamed; why should you not merely cut across the vena saphena, and put on pressure?” He was mistaken in his view of the matter, which was not indeed much understood by surgeons at that time. We now know that the veins after amputation not unfrequently inflame, and that this is one of the most common causes of death after amputation. When I was first assistant-surgeon there was a man with very bad varicose veins; such a case as those in which the vena saphena would formerly have been tied. I did not tie the vein, however, but I followed Mr. Abernethy's advice, cutting it across, and applying a compress and bandage. The patient had venous inflammation, attended with very severe typhoid symptoms, and died within four days after the operation. Since then, as you may suppose, no operation has been performed on the vena saphena, either by ligature or in any other way. There are no circumstances here to justify the performance of a dangerous operation. You may perform dangerous operations to get rid of a disease still more dangerous, but you have no right to perform an operation attended with such a degree of danger as can be appreciated, in order to get rid of a disease which is not dangerous; and no one can say that varicose veins belong to the class of dangerous diseases. But still there is another reason against having recourse to this operation. I do not believe, from any thing that I have formerly seen, that the operation permanently benefited the patients. It is true that they appeared to go away a great deal better, but I now and then saw one of them a year or two afterwards, and I always found them as bad as ever. Indeed I am by no means certain that the benefit which the patient appeared to derive, in the first instance, was the result of the operation; and I am more inclined

to believe that it arose from his having been necessarily kept for some time in bed in the horizontal posture. Patients always appear to get better under these circumstances. But I may observe further, that there appears to be no reason why in ordinary cases of varicose veins the obliteration of the saphena major should do any good, and that there are better grounds for believing that it will do harm. If you stop the vena saphena major you prevent the due return of blood to the heart, so that it is likely that the veins will become worse than they were before. Have I not shewn to you that pressure on large venous trunks causes an obstruction of the blood in passing through them? that this is one common cause of varicose veins? In *very bad cases*, however, of this disease, I can understand why the patient should derive benefit from trying the vena saphena major; and in order that you should understand what I now state, I must explain to you the different condition of the parts where the veins are very much dilated, and where the disease has only proceeded to a limited extent.

If the veins are but little dilated, or dilated only in particular places, the valves can still continue to answer the purpose for which they are designed. If the vena saphena major be not at all dilated, while the smaller veins of the leg are dilated, the valves of the vena saphena major act perfectly, and take off the weight of the column of blood pressing on the veins below; but if the vena saphena major be itself considerably dilated, its valves then are of no use. I have sometimes seen a very curious result from this. I had a patient, for example, in whom there was an unusually large cluster of varicose veins on the inside of the leg, while the vena saphena major was of enormous diameter, so that the valves could evidently be of no use. If I put on a bandage and squeezed the blood out of the veins below, and then put my thumb on the vena saphena major above, so as to stop the circulation through it, I found, on taking off the bandage, the patient being in the erect posture, that the cluster of veins below filled very slowly from the capillary vessels. But if, the patient being in the erect posture, I took off my thumb from the vena saphena major, the valves being of no use, the blood seemed to flow down from the trunk of the vena saphena major, contrary to the circulation, and filled the varicose cluster below almost instantaneously. I can understand that a ligature upon the vena saphena major, under these circumstances, would in a great degree lessen the inconvenience arising from the distension of varicose veins below. It would answer the same purpose as the pressure of my

thumb, but still it is not to be supposed that the good thus obtained would counterbalance the chance of mischief resulting from the operation.

I was occupied, many years ago, in making experiments on the obliteration, not of the vena saphena, but of the veins themselves. I applied caustic so as to penetrate through the skin to the veins, and in this way I cured many varicose ulcers. Mr. Mayo has, as I have been informed, employed the same practice lately, with this difference: he has not gone far enough to make a slough of the vein, but brought on some inflammation which has caused the vein to become obliterated. I tried this method in many cases, but I cannot say that I have found it answer sufficiently to make it worth the patient's while to submit to it. The application of the caustic was very painful, the slough took a long time to separate, the sore took a considerable time to heal, and though one cluster was cured, other clusters appeared. Altogether it was a very tedious process, and my own experience does not lead me to recommend it.

Then I contrived another method. Though there is danger in cutting across large veins, or in tying them, there does not appear to be any danger which can be appreciated from the ligature of smaller veins. Piles are nothing originally but varicose veins; now I have performed operations for internal piles, I cannot tell you how often, for there is nothing in the practice of surgery more common; but I have never yet seen a patient have venous inflammation arising in consequence.

We frequently cut across small veins in operations, and they are divided by accident, but we never find venous inflammation supervening. Although there may be danger from operations on the vena saphena major, we have no right to expect danger from operations on the smaller veins. I contrived, then, the following method. Supposing that I intend to cure a particular cluster of veins, I use a sharp-pointed bistoury, which cuts, not like a common bistoury, on the concave, but on the convex edge. I puncture the skin with this instrument on one side of the varicose cluster; I carry the blade under the skin, between it and the varicose veins, over to the other side of the cluster; and having carefully performed this part of the operation, the skin over it remaining entire, except where the first puncture was made, I turn the edge of the instrument backwards, and drawing it out, cut across the cluster. A good deal of hæmorrhage follows, but the pressure of a compress commands it, and a bandage is applied afterwards. The wound, in most instances, heals by the first intention. The varicose

veins are obliterated, and usually in a few days the patient suffers no inconvenience from the operation. However, in some cases, the wound suppurates, instead of healing by the first intention, which protracts the cure. Then, in other cases, a remarkable occurrence took place. Although I was satisfied that the cluster was divided, the disease was not cured. It seemed as if the veins healed without being closed. As the ductus choledochus, or the intestinal canal, will heal after the application of a ligature, without the continuity of the canal being destroyed, so it appeared that the continuity of the canal of the veins was not in every instance obliterated.

This was a very easy and a very safe method of curing varicose veins, yet we hardly ever perform this operation now; for, with my present stock of experience, it really seems to me that there are very few cases in which it is worth the patient's while to submit to it. I have always observed that if I have cured one cluster, two smaller ones have appeared, one on each side, so that ultimately I left the patient no better than I found him.

The operation, however, is proper where there is a varicose cluster much distended, and liable to burst and bleed. Here you may actually save the patient's life by having recourse to it; and you may do so without considering whether fresh clusters are or are not likely to form afterwards. Sometimes when there is a varicose cluster above and below on which a varicose ulcer depends, you get the ulcer to heal sooner than it otherwise would by dividing the cluster. I do not recommend this generally in cases of varicose ulcer, but only every now and then where there is unusual difficulty in getting it to heal. I generally observe that it heals sooner if you divide the cluster below than the cluster above. Then there are some cases where a varicose cluster is productive of an unusual quantity of pain, apparently in consequence of there being some nervous filament lying over it which is kept on the stretch. There you may relieve the patient from the pain of the particular cluster by the division of it. But these occasions are of rare occurrence; and under other circumstances I really do not think that it is worth the while of any patient to submit to the operation.

I ought not to take leave of the subject which is before us, without referring to a very ingenious method of obliterating varicose veins, which has been lately adopted by M. Velpeau, of Paris. He introduces a pin or needle through the skin, which is passed underneath the vein, and at right angles to it. A twisted suture is then applied round the two ends of the pin, so

as to compress the vein sufficiently to produce its obliteration. I cannot, from my own experience of this practice, say any thing of its advantages or disadvantages; but must acknowledge that it seems not improbable that it may be preferable to the other methods of which I have given you a description. Still, the observations which I have made as to these other methods, apply equally to this. It may be useful in certain cases, and under peculiar circumstances; but I can see no reason to believe that you would be justified in having recourse to it on ordinary occasions.

GUY'S HOSPITAL PHYSICAL SOCIETY.

November 4, 1837.

DR. HUGHES IN THE CHAIR.

DR. ASHWELL read a paper on—

Hæmorrhage from the unimpregnated Uterus, associated with Tumors of varying degrees of Induration and Malignancy.

Dr. A. remarked that the following points, in reference to these growths, deserved especial attention. First, They commenced in the parenchyma of the organ, or, in other words, from the tissue or structure inclosed within its peritoneal and mucous coverings, in closer proximity to the mucous than to the peritoneal coat. Hard tumors have more commonly been thought to commence between the muscular and peritoneal coats.

2dly. When they produced the hæmorrhage now alluded to, they grew internally, not imbedding themselves in the walls of the uterus and advancing towards the peritoneum, but by their increase in size partially distending the uterine cavity, and not only stretching and irritating the mucous membrane, thereby altering its condition and deranging its functions, but also gave rise to morbid growth of this tissue; in some measure proportionate to their own bulk.

3dly. They had generally the white lines and the hardness indicative of schirrus, or they possessed a more decided degree of malignancy.

In answer to various questions,

Dr. A. alluded to the cases adduced (four in number), to the preparations, and the drawings; stating that this location of the growth was very singular, and not, as supposed by some, "a matter of such common observation as to be familiar to every one."

In Guy's Museum, out of thirty examples of hard fibrous or schirrous tumors,

twenty-six were situated in some parts of the walls, while only three, or at the most four, were lodged within the cavity. Dr. A. also pointed to the difference between the growths partially and morbidly distending the cavity, as now described, and those entirely filling it up: these latter would probably prevent hæmorrhage by their pressure.

A section of one of the tumors, with a drawing executed by Canton, was shown to the Society.

The tumor was distinctly of a cystiform character, about the consistence of firm steatoma, encroaching on the uterine cavity, which was thus rendered uneven, but still capacious. The mucous lining itself was free from any visible lesion, but was highly vascular, and a web of vessels was seen on that part which was stretched across the tumor. The vascularity of the mucous lining, and the total absence of vascularity in the tumor itself, led Dr. A. to regard the former as the source of the hæmorrhage in question, while the latter, by its mechanical action, operated as the exciting cause of such loss of blood. This difference in the source of hæmorrhage, as observed in polypus and in the tumors alluded to, was a fact to which Dr. A. called the particular attention of the Society.

In the course of the discussion that followed, the question of the malignant or non-malignant character of these hard tumors of the uterus came under the consideration of the Society. It was contended by Mr. Greenwood, Mr. Bransby Cooper, Mr. Roberts, and others, that the evidence and arguments adduced by Dr. Ashwell tended rather to shew that these tumors were non-malignant. Their long-continued quiescent state—the absence of local pain, or constitutional suffering—the exemption of other parts, such as the lumbar and absorbent glands of the pelvis, from a like affection—the age at which they usually occur—and the alleged curability of these structures by means of iodine, as stated by Dr. A., all went to prove that they were at least different from truly malignant diseases elsewhere. To all this it was replied by Mr. Oldham, Dr. Ashwell, and others, that the indolent state of these tumors depended very much upon their situation. When placed in the parietes of the womb there was much space for their growth, and in the absence of exciting causes they remained sometimes years without change. Under the influence, however, of an exciting cause, such as pregnancy, their malignant character was fully developed, and hence Dr. Ashwell had been induced to recommend the adoption of premature delivery in such cases. In glandular parts, too, as in

the cervix uteri, malignant ulceration quickly attacked these tumors. Examination of their structure also shewed that they were of the cystiform character supposed to belong to malignant disease. With regard to age, cancer often occurred in very young persons, and several cases were adduced whose age at the time of death was under thirty years. Dr. Ashwell further strongly vindicated the use of iodine in resolving these tumors, especially when situated in the cervix uteri, by which remedy he was satisfied that ulceration was often prevented, and their increase arrested to an obvious extent.

Other topics of discussion also arose in the course of the evening, in which the proposal to induce premature delivery in cases of pregnancy associated with hard tumors, was canvassed by Mr. Law, Mr. Lever, Mr. J. H. Roberts, &c.

The opinion of Sir Charles Clarke upon the nature, history, and treatment of these diseases, were introduced by Mr. Gazelee into the discussion; but a difference of opinion occurred between that gentleman and Dr. Ashwell as to the true interpretation of Sir C. Clarke's expression. At the termination of the discussion (which was highly animated), a vote of thanks to Dr. Ashwell was unanimously accorded by the Society, upon the motion of Mr. Greenwood, seconded by Mr. B. Cooper.

At the next meeting of the Society, Saturday, Nov. 18, at eight, p.m., Mr. EDWARD COCK in the Chair, Mr. EDEN will read a paper on "Normal and Abnormal Dentition."

PROVINCIAL MEDICAL ASSOCIATION.

PETITION AGAINST THE POOR-LAWS.

In the course of their proceedings at Cheltenham, the "Provincial Medical and Surgical Association" agreed upon the following petition, to be presented to both houses of parliament immediately on their assembling. This was done on the motion of Dr. Webster, of Dulwich, seconded by Mr. Addison.

COPY OF THE PETITION.

The Petition of the President, Council, and Members of the Provincial Medical and Surgical Association, assembled at the Fifth Anniversary Meeting, at Cheltenham,

HUMBLY SHEWETH—

That your Petitioners deprecate the system of medical relief adopted by the Poor-Law Authorities.

That the greatly diminished and insuffi-

cient supply of medical officers must lead to the neglect and injury of the sick poor, and to the increase of those monopolies of parochial practice which were among the acknowledged evils of the old system.

That the extent of medical districts, in general, precludes that prompt and convenient performance of medical duties which is essential to the proper treatment and the safety of the sick paupers.

That the procuring of medical officers by public advertisement and "tender" (a practice degrading to the profession), is injurious to the public, because it cannot afford a sufficient test of the qualifications and practical skill of the candidates, and, consequently, is not calculated to provide humane and efficient attendance for the sick poor.

That dietating, either with or without tender, stipends far below the conventional value of the services required, and any rational calculation of their cost, with the alternative of the introduction of strangers, is another mode of competition equally unfair to the resident and experienced practitioners, and unjust and injurious to the poor.

That vesting in the hands of the relieving and parish officers the power of deciding whether the sick pauper requires medical aid, is calculated to prolong disease and endanger life.

That entrusting to non-professional persons, such as Poor-Law Commissioners, and Boards of Guardians, the power of superintending and controlling, justifying and condemning the conduct and proceedings of the medical officers, is neither just nor judicious, and is not in accordance with the practice pursued in other departments of the public service.

That as the entire system is unjust and derogatory to the medical profession, detrimental to science, injurious to the community, and cruel and delusive to the sick poor, your Petitioners humbly but earnestly hope that your Honourable House will be pleased to direct a special, complete, and impartial inquiry into the subject of medical relief, and grant an order for the production of official returns of all medical contracts made under the Poor-Law Amendment Act; of the number of medical officers appointed, as compared with the former system—of the extent of their respective districts—of the amount of their salaries—of the mode of their appointment—of the number of patients attended, and visits performed by each medical officer; and, finally, enact such remedies as to your wisdom shall seem fit.

And your Petitioners, as in duty bound, will ever pray, &c.

(Signed) H. C. BOISRAGON, President.

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Mr. LUKE, Surgeon.

Mr. CURLING, Assistant-Surgeon.

Oct.	Sex.	Age.	Case.
24.	M.	56	Fractured ribs.
	M.	29	Contused foot.
	F.	40	Sprained ankle.
25.	F.	16	Bite on the ankle.
	M.	72	Large scrotal hernia (reduced.)
	M.	40	Concussion.
	M.	37	Sprained ankle.
	M.	56	Fractured femur.
26.	M.	28	Contused back.
	F.	33	Fractured femur.
27.	M.	30	Fractured ribs.
	M.	68	Contused wound of the eye, with slight abrasion of the cornea.
	M.	32	Contused leg.
28.	M.	17	Contused shoulder and back.
29.	F.	48	Small femoral hernia (reduced.)
	F.	37	Femoral hernia (operated on, (a.))
	F.	18	Cut hand, with division of the radial indicis.
30.	M.	50	Cut head.
	M.	28	Sprained ankle.
31.	M.	82	Fractured neck of the femur.
	M.	45	Compound fracture of the right tibia and fibula, and simple fracture of both bones of the left leg. A slight wound at the back of the head, (b.)

In-patients 21
Out-patients 42

Total 63

(a.) In this case strangulation had existed for twenty-eight hours, and a large portion of omentum contained in the sac was in a state of sphacelus; it was therefore excised. The bowels were not moved till twenty hours after the operation; but all inflammatory symptoms have subsided, and the patient is doing well.

(b.) This patient, a drayman, was thrown from the horse on which he was riding sideways upon some gravel. He was brought to the hospital in a state of great prostration. The lower part of the right tibia was fractured obliquely, and there was considerable displacement of the ends of the bone, which it was impossible to reduce. There was a wound three inches in extent about the middle of the tibia, and a small one of about half an inch at

the fractured part. From both wounds venous hæmorrhage ensued, and, notwithstanding the employment of pressure, continued till the evening, during which time the man must have lost about thirteen ounces of blood.

On the 31st the femoral artery was tied in a spare unhealthy-looking man, aged 39, on account of the sudden rupture of the true sac of a popliteal aneurism. The patient is supposed to have hypertrophy of the left ventricle of the heart; and in the evening the impulse at the seat of the ligature was so violent, that it was thought advisable to bleed him, which was repeated the following day. At present, Nov. 5, he is going on well.

BORATE OF SODA IN DYSMENORRHOEA

DR. DANIEL STAHL, of Vincennes, Indiana, highly extols, in a communication to the *Western Journal of the Medical and Physical Sciences*, (April, 1837,) the efficacy of Borax in the treatment of Dysmenorrhœa. It is not, however, recommended to be given indiscriminately, or without preparing the system for its reception.

"In lymphatic constitutions, and with patients who are debilitated by other diseases," says Dr. S., "the effect is often doubtful, at least not very prompt; whereas in patients of sanguineous or sanguinonervous constitutions, and where there is an actual plethora, it will always be found effectual if venesection be premised. We should never give it without bringing all the systems of the organism to a kind of equilibrium; therefore bleed and give antiphlogistics in plethoric constitutions, raise the energy of the nervous system in 'nervous subjects,' and give tonics to the debilitated.

"After many trials with borax, I determined on the following plan of treatment, and follow it now exclusively.

"In plethoric habits*, I take from four to six ounces of blood from the veins of one of the lower extremities, and repeat the venesection if necessary, and keep the bowels open by Epsom salts. For two days previous to the appearance of the menses, I order a warm foot bath every evening and morning, and give borax in the following formula:

"R. Natri. borac, ʒii.; infusi semini lini. ʒvii. Misce: every two hours a table-spoonful to be taken.

"The pain I relieve by extractum

hyoseyami*, one grain every fifteen or thirty minutes.

"In nervous habits, where I find this complaint in four cases out of seven. I commence my treatment with the exhibition of tinctura valerianæ, teaspoonful doses thrice a day, and previous to the appearance of the menses, I give borax, &c. as above.

"As soon as the menstruation ceases for the time, I treat plethoric habits with slight antiphlogistics, and with the nervous I resume the use of tinctura valerianæ until a day or two previous to menstruation, when I act as before. After the second appearance of the menses, after following that plan, I will generally hear the patient relate with gratification, that the pain was less and of shorter duration, that she menstruated more than usual, and that she feels more contented and cheerful†, and by the third time, the complaint, the mere idea of which haunted the poor woman from one period to the other, is generally removed."

MR. BAKER'S SUBSCRIPTION.

To the Editor of the Medical Gazette.

SIR,

As one of the subscribers to the fund raised under the auspices of that clever and industrious gentleman, Mr. James Baker, for defraying the expenses attending the petitions to parliament respecting the "Medical Witnesses' Bill," I beg to inquire, through the medium of your excellent GAZETTE, how it happens that no public statement whatever of the disbursements has yet appeared, and the more so, as I was induced to advance my money solely on condition that a faithful account of all receipts and payments should be rendered immediately after the affair should be completed. Perhaps, Mr. Editor, some of your numerous readers can inform me whether any such document is likely very shortly to be produced; because if I do not obtain, through your widely circulated GAZETTE, an immediate reply in the affirmative, I shall most certainly take the proper steps to convene a public meeting of the subscribers. Really, Mr. Editor, I have been so repeatedly and shamefully bamboozled out of my money,

* In some cases the extr. hyoseyami produced nausea, and if there was no contraindication I gave Dover's Powder, or what was the most effectual, Aqua Laurocerasi.

† In most cases of dysmenorrhœa menstruation is scanty, and symptoms of hysteria are present.

* It is very rare to find dysmenorrhœa in plethoric habits.

under one pretence or another, that I am positively half inclined to view this matter as a mere job, notwithstanding all the fine professions of disinterestedness made to me by Mr. Baker, when he so earnestly solicited my pecuniary aid in this good cause; and therefore I shall not choose to remain any longer quiet, unless the business is cleared up to my entire satisfaction without loss of time.

Rest assured, that in these sentiments I am joined by many most respectable and influential members of the profession, who parted with their money under the same impression as myself, and who now feel exceedingly indignant at the non-production of any account from Mr. James Baker, who, from his standing as a medical practitioner, can have no pretensions to act in so disrespectful a manner towards his colleagues. Under these circumstances, I feel well persuaded that the immediate insertion of the present communication in your *GAZETTE* will be appreciated as a favour conferred on the whole profession.—I am, sir,

Your most obedient servant,

AN ENEMY TO HUMBUG.

Tuesday Morning,
Nov. 7, 1837.

P.S.—Your estimate of Mr. Baker, as expressed in your journal about October 1835, and the opinion of the Apothecaries' Company, as shewn by their legal proceedings against him, still pending, have most clearly demonstrated that your severe strictures on his conduct were richly merited by him.

BOOKS RECEIVED FOR REVIEW.

LECTURES

ON THE

PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE VII.

Physical Examination of the Chest (continued)
—*Sounds of Respiration (continued)*—*The Rhonchi*—Dry Rhonchi, Sibilant, Sonorous, Dry Mucous—Humid Rhonchi, Mucous, Cavernous, Submucous, Subcrepitant, Crepitant—Importance of the Rhonchi as Signs—*Sounds of the Voice*—Natural Sounds, their causes and regions—*Morbid Sounds*: Bronchophony, Ægophony, Pectoriloquy, Metallic and Amphoric Resonance, Pectoral Frenitus—*Sound of Friction*—*Tabular View of the Sounds of the Organs of Respiration.*

WE have hitherto considered the sounds produced by the passage of the air to and fro in the lungs, and we found that the varieties of these sounds depend on the size of the tubes and on the force with which the air strikes against their sides and angles, and that they may be shortened or stopped by various kinds of obstruction.

We have now to attend a little to a class of novel sounds which arise from partial obstructions to the passage of air,—obstructions which permit the air to pass, but not without such a resistance as causes an increased and modified sound. Thus,

suppose a bronchial tube to be narrowed by the swelling of its membrane, or by mucus secreted by it, the air must pass through the narrowed portion with increased velocity and increased resistance, and hence the sound is changed from a simple breathing or blowing, to a louder wheezing, bubbling, whistling, or snoring, according to the nature of the obstruction. These new sounds Laennec called *râles*, or rattles; I have preferred the Latin term *rhonchus* (which is from the Greek *ῥογχος*), as more expressive, and this has been adopted by most English writers. I wish we had an English word that would do as well; for nothing injures the purity of a language more than the introduction of foreign words: and it is only pedantic to use them when English terms will express the same thing. And here, in relation to our subject, I enter my protest against the prevalent use of French words, in English speaking or writing, such as *bruit de soufflet*, *bruit de râpe*, *bruit de pot fêlé*, *frôtement*, *gargouillement*, *tintement métallique*, &c.;—the simple translation of which would do just as well, and convey much more precise and intelligible ideas than these mystifying terms. We cannot, however, do well without the word *rhonchus*, or some other to be used conventionally in the same sense, as a generic term applicable to all those sounds which are produced by an increased resistance to the air moving through the lungs.

Let us attend to some of the species of rhonchus. I divide them into the *dry* and the *humid*, according to whether the impediments that produce them are solid or liquid. Of the dry rhonchi there is the *sibilant* or *whistling rhonchus*, which is sufficiently described by its name, and may be generally imitated by whistling between the teeth. It is produced by the passage of air through a small and rather circular aperture; and this aperture may be formed by a slight obstruction of a small tube, or

by a greater obstruction in tubes of larger size. It generally occurs in tubes narrowed by swelling of their mucous and submucous coats, such as occurs in the early stage of acute bronchitis; but you have it also in asthma, where the tubes are congested and constricted by the spasmodic contraction of their circular fibres; and you may have it also when viscid mucus clings to and diminishes the calibre of the tubes.

The *sonorous rhonchus* is a snoring, humming, or droning sound, and may vary in loudness and key from an acute note like that of a gnat, down to the grave tone of a violoncello or bassoon. It must be produced by obstruction leaving a flattened aperture, the lips of which, or the moisture on them, yield to the passing air with a vibrating resistance. Partial swelling of the sides of a tube, particularly at its bifurcation, a pellet of tough mucus in it, or external pressure on it, may cause such a flattened opening within the tube; and the sound in question therefore occurs in various forms of bronchitis, and often accompanies tumors which press on the bronchial tubes. When caused by tough phlegm, coughing will generally change or remove it; when from the other causes, it is generally more permanent. When quite permanent, it usually depends on the pressure of a tumor or some deposit outside the tube. The key of this note depends chiefly on the size of the aperture left; when this is small the note is high, when large the note more of a bass: from this we may infer that the latter can only have its seat in the larger tubes; but as a more considerable obstruction may flatten their calibre to the smallest size, these may also be the seat of the acute notes. You may imitate almost every variety of this rhonchus by blowing between the lips moistened with saliva and almost closed. This is the mode in which M. Alexandre imitated the buzzing of a fly.

There is another rhonchus which I call the *dry mucous*, because it is produced by a pellet of tough mucus obstructing a tube, and yielding to the air only in successive jerks, which cause a ticking sound, like that of a click wheel. When the air is driven very fast, these, as in the case of other click-sounds, pass into a continuous note, and constitute the *sonorous rhonchus*. Sometimes, again, particularly in inspiration, the click-sound suddenly stops; the tough mucus being forced into a smaller tube which it completely closes, and may not be dislodged again, but by dint of forcible coughing.

Now, as any of these rhonchi may be produced in only one tube and yet make a great deal of noise, you are not to suppose that they are important in proportion to

the noise they make. It is rather when they are very permanent, or when several of them are heard at once in different parts of the lungs, that they bespeak disorder which may be serious, either from its permanency or its extent.

The *humid rhonchi* all depend on the passage of air, in bubbles, through a liquid in the lungs, and their species are produced by differences in the size of the tubes, and the nature and quantity of the liquid, which cause varieties in the bubbling sound. Do not suppose I am trifling with your time because I ask your attention to some of these *bubbles*. Newton learnt much by studying the colour of a soap bubble, and he still left much in it for others to explain: perchance, we may learn somewhat by studying the sound of the bubbles in the lungs; at least we should lose nothing, as others do, by their *bursting*. A bubble is a portion of air contained and slightly compressed by a thin film of liquid, which preserves its continuity by its molecular or aggregative attraction: when this attraction is overcome, by the gravitation of the liquid, the motion of the air, or any other disturbing cause, the bubble bursts: as it bursts, the air from it, slightly expanding, gives to the adjacent air an impulse, which, if forcible enough, produces sound. In the bubbling passage of air through a liquid, the air is the moving body; the liquid gives the resistance, and in proportion as these are strongly and suddenly opposed to each other, the louder will be the sound produced. If the air pass with force it will make most noise in a liquid of some tenacity which offers to it most resistance; but if it move slowly, such tenacity may retard the breaking of the bubbles, and therefore diminish the sound. Again, air passing through liquid in large tubes will give most sound when the liquid is thin, because the bubbles form and burst quickly; but in passing through very small tubes air will cause more sound with a rather viscid liquid, which, adhering to the tubes, is not carried before the air so readily as one of a thinner nature. Now, let us apply this rule to the bubbling sounds or rhonchi heard in the chest.

The *mucous rhonchus* may be heard in the large and smaller bronchi down to the size of a crow's quill, and in these different situations its gurgling or crackling presents different degrees of coarseness. It is an irregular and varying sound composed of unequal bubbles, and generally interspersed with some whistling, chirping, or hissing notes. Its most common cause is acute bronchitis, which after its onset is attended with a secretion of liquid mucus into the bronchial tubes; and the passing of the sibilant and sonorous rhonchi of the

first or dry stage into the bubbling of the second or secreting stage is often marked by a curious combination of chirruping and cooing notes, like those of birds in a bush. When the bronchial tubes become unnaturally enlarged by disease, or when morbid cavities are formed by the destruction of portions of lung, the bubbling of air through liquid in these, is of the coarsest kind; it is quite *gurgling*, and if the liquid be scanty, has a hollow character, and is called the *cavernous rhonchus*.

When there is a little liquid in the smaller bronchi the bubbling or crackling is more regular, although the sound is weaker, and is sometimes only a roughness added to the ordinary respiratory murmur. This is the *submucous rhonchus*. It may result from slight degrees of bronchitis, and owes its importance only to its being permanently present when such slight inflammation is constantly kept up by the irritation of adjacent tubercles in an incipient state.

When there is more liquid, not viscid, in the smallest tubes and terminal cells, the rhonchus has a still more crepitant character, and resembles that heard on applying the ear near the surface of a liquid slightly efferverscing, such as bottled cyder or champagne. This is the *subcrepitant rhonchus* which is heard in œdema of the lungs, humid bronchitis, and other affections in which liquid and air occupy the extreme tubes, and are forced through each other in the motions of breathing.

But the most perfect and equal crepitation is that of peripneumony, called the *crepitant rhonchus*. It exactly resembles the sound which you can produce by rubbing slowly and firmly between your finger and thumb a lock of hair near your ear. I believe that this sound depends on the forcible passage of air through a little viscid liquid in the finest tubes narrowed by congestion and deposit around them: but we shall speak more of this when we come to treat of peripneumony.

Of all these different rhonchi we may say what we did of the morbid sounds of respiration, that they may occupy the whole of the respiratory movements, or be confined to part of them. Thus an obstruction which is sufficient at the commencement of inspiration to cause a rhonchus, may be insufficient when the tubes are dilated by the distension of a full breath; and you may have the converse, an obstruction which is total in low degrees of respiration and stops all sound, in forced and extensive efforts, as in coughing, occasions a rhonchus. This suggests to us the propriety of using these different degrees of respiration to test the nature and extent of bronchial obstructions. You may also

gather from what has been said that the different stages and degrees of force in respiration may change the note of the different rhonchi, and thus produce a variety of music, which we do really hear in the chests of some catarrhal and asthmatic patients. Laennec used to call this piping sound, *rhonchus canorus*. After the explanations which I have given, you may easily perceive that these several rhonchi may be variously combined, or exist at the same time in different parts of the lung, and give rise to numerous combinations that I need not dwell on. I before observed that the loudness of a sonorous or sibilant rhonchus is no proof of the severity of the disease, nor is the fact of its being audible over the whole chest, unless the respiratory murmur be at the same time absent, or very feeble in parts. But the presence of the bubbling or crepitant rhonchi does imply mischief proportioned to its extent; and if they are heard over a large space, and accompanying the whole act of respiration, diminishing or destroying the natural respiratory murmur, they denote disease of a very serious character, because, as your hearing informs you, there is an obstructing liquid in the tubes, where there ought to be only air.

So much for the sounds produced by the passage of air.

We have now another class of sounds to examine—the sounds of the voice as transmitted through the chest. We have found that sounds produced by air passing in the lungs are transmitted to the ear on the surface of the chest; and why should not the sounds of the voice, which are strongly communicated to the same air, be transmitted in like manner, modified by the size of the tubes, and the nature of the substance through which they pass? So in truth they are, and if carefully attended to, they may thus become signs of the condition of the organs that transmit them.

If you apply your ear to the throat, or upper part of the sternum, of a person whilst he is speaking, you will hear the voice so loud that you might fancy he was speaking into your ear, only the articulation is not as distinct. The reason of this is plain enough. The sound of the voice, although originating in the vibration of the glottis, is propagated to the air above and below it; that below being pent up is not heard without bringing the ear into contact with the parts where the tubes run, and it there resounds with all its force. This is called *tracheophony*, or the natural tracheal voice.

But when the trachea divides and subdivides, there is not only a splitting of the

vocal sound into smaller pipes, and a consequent diffusion of it, and a reduction of its volume, but at this division the tubes plunge into the spongy tissue of the lung, which, as we have before found, is a bad conductor, and tends to stop the sound. Hence, over the chief bronchial ramifications, as on each side of the upper part of the sternum, at and between the scapulae and in the axillae, you still hear the voice, but it is less in a body, more diffused and more distinct, than in the other parts, and the articulation is still less distinct. This is natural *bronchophony*, or bronchial resonance.

What becomes of the voice in other parts of the chest? Why, as it gets into the finer tubes with their more flaccid coats and minute cells, its vibrations are either choked and destroyed, or in some parts may be transmitted across the tissue to the parietes in merely an obscure diffused *fremitus*. This I call the *pectoral fremitus*. It may be also felt by the hand applied on the chest.

Now before we touch on the modifications of these sounds by disease, I must say a few words on some natural varieties and their physical causes.

Natural *bronchophony*, or the vocal resonance in the bronchial tubes, is most distinct in thin persons with a high or treble voice, as in females and children. Shrill or treble notes penetrate further into the small tubes, because their vibrations are less excursive and need less room than those of a deeper tone. You remember how we noticed this difference in the cords of the guitar. The motions of the treble cords were so short and quick that you could scarcely see them, whilst those of the bass were long and comparatively slow. Now what will be the effect in a person with a bass voice? Why, the voice will scarcely go into the subdivisions of the tubes, and there will be little or no *bronchophony*; but if the voice be strong it will not be entirely lost, for it will pass *across* the whole spongy tissue, and throw it all more or less into a diffused vibration, which will be heard and felt in many parts of the chest, in the character of *pectoral fremitus*. We find, then, that treble tones of the voice give more of *bronchophony*, and bass ones more of the *pectoral fremitus*; and the same occurs with the morbid sounds: if we can get our patients sometimes to change their tone of voice, we may thereby more effectually test the condition of their pectoral organs.

Now, as with the corresponding varieties of respiratory sound, so with these sounds of the voice, they become signs of disease when they are heard out of their

proper places. But you will say, as there is some natural variety in different individuals, how shall we know what are their proper places? The diagrams which you see here, and in my work on *Diagnosis*, before mentioned, and your own anatomical knowledge, will guide you in a general way on this point, by pointing out in what regions the different sized tubes lie; but there is another standard more applicable to individuals, and that is, comparison between the two sides of the chest. As there is an approach to symmetry in the structure on the two sides, so there is in health a general correspondence between their sounds; and as disease scarcely ever affects both sides at the same time, or in the same degree, it will make the phenomena of one side to differ from those of the other. For example, if under one clavicle you hear the voice resound loudly, whilst it is scarcely heard under the other, you may be sure that there is some physical difference between the two sides, which does not exist naturally; or if you hear below the third rib in front the tubular or bronchial voice, which is generally confined to the immediate neighbourhood of the large bronchi, you may also infer that there is an altered condition of the parts. And now let us see what alterations will change the natural disposition of the sounds.

Increased density of the pulmonary tissue by solid or liquid effusion, or even great sanguineous congestion in it, will improve its conducting power, and will enable it to transmit from the bronchial tubes within, the vocal sounds which they receive from the trachea. This is *morbid bronchophony*, and it is usually accompanied with bronchial respiration. Well, then, if you hear the voice resounding in a part of the chest where it is not usually heard, you may suspect the lung there to be somehow increased in density; but you cannot be sure until you shall have tested this by other means, for there is another change which may have a similar effect. If, instead of the sound being better conducted from within, it is increased in strength and extent by an enlargement of the bronchial tubes, it may then be heard in situations where it does not naturally reach the walls of the chest. In both cases it may more or less resemble the natural *bronchophony* heard near the top of the sternum and between the scapulae; but it often presents remarkable modifications. Thus, when transmitted from the middle-sized bronchi, it comes rather as *diminutived bits of voice* than as articulate words; and for reasons before mentioned low tones are not transmitted; so that if the patient varies his cadence, some words

are heard, and others not. When arising from dilated air-tubes, or when transmitted from the larger tubes, the resonance is more noisy and continued, varying less with the tone of the voice. If the air-cells over the resonant tubes are still open, the sound will be diminished when they are dilated by a full inspiration, because they then tend to intercept it more. The loudest bronchophony is caused where the middle or upper parts of the lung are pressed against some part of the walls of the chest by a liquid effusion in the pleura, which cannot displace the lung from that part, because it is bound to it by old adhesions.

But what modifies the transmitted voice in the most remarkable manner is a thin layer of liquid between the lung and the walls of the chest. The liquid is thrown by the vocal resonance of the lung into a state of irregular vibration, which causes it to transmit the voice in a broken tremulous manner, so that it sounds to the ear outside like the bleating of the goat. Hence Laennec called it *agophony*. It may be produced simply by liquid in the pleural sac, without disease of the lung; for the compression of the pulmonary tissue caused by the liquid is enough to enable the lung to transmit the voice from the bronchial tubes within it. When the lung is consolidated also by disease, the vocal resonance is stronger, and there is a loud bronchophony mixed with the bleating voice, constituting a kind of buzzing voice, which Laennec compared to that of *Punch*.

But there is another kind, which may be called the perfection of vocal resonance, in the chest. When a cavity is formed in the lung by the emptying of a vomica or abscess through the air-tubes, the voice will pass from these tubes into it; and if the communication is free, the voice may, by the ear applied outside, be heard in the cavity as loud and distinct as it is in the trachea. This is *pectoriloquy*—not only *voice*, but *speaking*, in the chest. When the cavity is near the surface, of moderate size, and opens freely into a large air-tube, the phenomenon is most perfect, and then sounds exactly as if the patient spoke into one's ear: this is limited to the spot where the cavity lies, which is thus, as it were, a little *island* of voice, and when so it is a sure sign of a cavity. The sound of bronchophony is often louder, but then it is more diffused, and there is less distinctness in the words. But I shall not now dwell on these distinctions, because we shall speak of them when we come to treat of the diseases which cause these phenomena.

When the cavity is large, and the opening into it small, the voice may not fully get into it, but there may be a hollow or tinkling reverberation in it, like that in a phial, which is one of the modified echoes from repeated reflection that I told you of in my lecture on sound. This is called *amphoric resonance*, or *metallic tinkling*, according to the character of the sound. It may be produced in the cavity left by a large vomica or abscess, or by several of these running together; but its more common seat is the sac of the pleura, into which air has entered through a fistulous opening from the lung. Now, this being the resonant or echoing cavity, you can easily perceive that not the voice only, but the breathing and cough also, especially if they be accompanied by a bubbling through the fistula, will have more or less of this tinkling or bottle sound.

Besides these various positive phenomena of the voice, the absence of the vocal fremitus is sometimes a valuable sign. I have said this pectoral fremitus can be felt as well as heard; and if you apply your hands, one on each side of a healthy chest, you will feel the vibrations on both sides alike. Liquid in the pleura will generally, more or less, destroy this fremitus, and the difference which it produces is often a very valuable sign of the presence of liquid. Consolidation of the lung, again, will increase the vibrations, or make them stronger over the bronchial tubes. In cases where one side is quite dull on percussion, you may often thus easily distinguish whether the dullness is caused by consolidated lung, or liquid in the pleura—a point of considerable importance in practice.

Besides these sounds produced by the air and the voice, you may sometimes have a sound produced by the motions of the lungs against the ribs. You know that the lungs, although they nearly follow the motions of the chest, do not move quite with it, especially in the lower parts, where the descent of the diaphragm draws the lungs downwards, whilst the ribs are rising. But in the natural condition, the surfaces of the pulmonary and costal pleura are so smooth, and so well lubricated with serum, that, although there is motion, there is not resistance enough to that motion to cause sound. But suppose these surfaces to become uneven by the deposit of rough matter on them, or by an irregular distension of the tissue by solids or air under them, you may then have a *rubbing sound* with the motions of respiration; and this does really occur in pleurisy and emphysema of the lung. This rubbing sound is often the more evi-

dent in these cases, because the same disease, by preventing the proper expansion of the lung, causes less harmony than usual between its motions and those of the chest.

Now, gentlemen, I have described and explained to you most of the acoustic phenomena of the chest connected with respiration. Those of the heart will be considered in the latter part of this course. Perhaps you may have thought me somewhat minute; I do not expect you to remember the details of what I have said; but if your understanding has accompanied me as I proceeded, you must have become pretty familiar with the *principles*, of which the various phenomena are illustrations. I would rather not encumber your minds with too many details, but I do wish to give you a sound knowledge of

the laws under which they occur; for from these, and a good knowledge of pathology, you may understand and deduce, not only the phenomena hitherto observed, but new forms and combinations of signs which observation and practice may bring before you. In our description of diseases we shall meet with these phenomena again; and from the principles which we have now developed, we shall be prepared for them wherever they may occur. In the mean time, I will leave for your inspection these tabular views of the acoustic phenomena of the chest, and the names by which they have been distinguished. They should be studied in conjunction with others which you will find at the end my treatise on the Signs and Pathology of Diseases of the Chest.

SOUNDS PRODUCED BY THE PASSAGE OF AIR IN RESPIRATION.

SOUND OF RESPIRATION.—*Natural*: produced by collision of the air against the sides and angles of the air tubes.

Tracheal; heard in the neck and at the top of the sternum.

Brachial; near the upper parts of the sternum, between the scapula, &c.

Vesicular; in most other parts of the chest.

Morbid, modified in production or transmission.

Bronchial, or whiffling; transmitted from the bronchi by condensed tissue of the lung.

Cavernous } produced in morbid cavities communicating
Amphoric } with the bronchi.

Amphoric } with the bronchi.

RHONCH, produced by increased resistance to the air moving through the lungs.

Dry; Sibillant Sonorous Dry mucous	} produced by viscid mucus in the bronchi, or by swelling of the membranes, or by pressure upon them.
--	--

Sonorous

Dry mucous

Moist; Mucous . . { produced by a bubbling } liquid in the bronchi.
 { passage of air through }

Submucous :

Subcrepitant	liquid in the smallest bronchi.
--------------	-----------	---------------------------------

Creepant viscid liquid in compress

elephant } smallest bronchi.

Cavernous liquid in a morbid cavity.

SOUNDS OF THE VOICE TRANSMITTED THROUGH THE CHEST.

NATURAL SOUNDS, *heard in a healthy chest.*

Tracheophony, in the neck and at the top of the sternum.

Branchophony, near top of the sternum, between the scapulæ, in the axilla, &c.

Pectoral fremitus, in many parts of the chest.

MORBID SOUNDS, transmitted or produced by a diseased chest.

Bronchophony, transmitted by condensed pulmonary tissue.

Ægophony, the same vibrating through a thin layer of liquid.

Pectoriloquy, resounding in a cavity in the lung.

Tinkling, a changed echo of the voice or cough in a large cavity.

SOUNDS PRODUCED BY THE MOTIONS OF THE LUNGS.

Sounds of friction, when the pleurae are dry, or rough from deposits.

Emphysematous crackling, by the irregular passage of air between the lobules.

LECTURES
ON
RHEUMATISM AND ITS EFFECTS;

BY R. MACLEOD, M.D.

Physician to St. George's Hospital.

LECTURE IV.

Synovial Rheumatism; its seat—Difference between it and the preceding form—Permanent Changes produced in the affected Joints—Nature of the Deposit—Carbonate of Lime, and Lithate of Soda—Suppuration in the Joints an occasional consequence of Synovial Rheumatism—Causes and Symptoms of the Disease.

If being different in their seat, in their symptoms, in their terminations, in the affections with which they are complicated, and in their treatment, be sufficient to prove that a distinction ought to be made between two diseases, then is rheumatism affecting the synovial membranes essentially distinct from the form of rheumatism already considered.

The seat of synovial rheumatism (as, indeed, the name implies) is in the lining membrane of the joints; being, in this respect, the same as gout, to which it is, in various respects, very closely allied. The parts most liable to its attacks are the feet and hands, where it is, for the most part, easily recognized by the enlargement of the small joints; but the peculiar characters of the disease are, perhaps, most strikingly displayed when it attacks the knees. At first there is pain and heat, which, in the more severe cases, are attended by external redness; and after a time, varying from about twenty-four hours to several days, tumefaction of the parts takes place. The appearance of the swelling, which is limited to the immediate vicinity of the joint, points out the nature of the affection. The effusion is within the synovial capsule, which is consequently distended, and projects at those points where it meets with least resistance. This gives a peculiarity to the shape, which at once strikes the eye. In the knee, the fulness is most conspicuous on either side of the patella and across the lower part of the thigh, just above the joint: frequently also it projects backwards, and may be seen or felt between the hamstrings. Even where the inflammation extends to the surrounding textures, they participate much less in this than in the preceding form of the disease, and the swelling is consequently much less diffused. In the synovial rheumatism the swelling is fluctuating, and bound down by the ligaments of the joint; in the common acute rheumatism, the effusion is external to the capsular ligament—chiefly in the cellular membrane—is not fluctuating, but occasionally pits very slightly, like inflammatory œdema. The shape and aspect of the two thus differ strikingly from each other.

Nor are the histories of the two diseases less remarkable for their points of difference. The synovial rheumatism is infinitely more persistent—affecting, for the most part, several joints, but generally becoming more especially fixed in a limited number, to be ultimately completely localized, and in a certain proportion of them to produce permanent changes of structure, or even disorganization of the parts. In general, it is probable that the effusion into the joint consists merely of an increased quantity of synovia, produced by the excited condition of the secreting surface. Such, at least, was the case in an instance wherein I very lately had an opportunity of examining the body of a patient cut off by another disease, while labouring under a first attack of synovial rheumatism. The joint chiefly affected was the knee; it contained an increased quantity of synovia, and the lining membrane, except where reflected over the cartilages, was of rather a deep red colour, and tumefied. But where the attacks have been repeated, or have expended themselves upon particular joints, much more considerable changes take place.

When the disease recurs several times, the recovery after each attack becomes less and less complete; the joint remains perceptibly swollen; the ligaments which bind the extremities of the bones together become stretched; the relative situations of the articulating surfaces are altered, and more or less distortion is the result. Sometimes the quantity of synovia in the joint becomes permanently, though not very considerably, increased, the disease assuming an entirely chronic character; and in several such cases, where I have examined the joints after death, I have found little or nothing which could be called disease, with the exception of a preternatural quantity of synovia. In others, the synovia, which, during the acuter attacks, becomes increased in quantity, is again absorbed as these subside; but about such joints, particularly after repeated attacks, some degree of thickening remains. This is most remarkable about the small joints, particularly those of the fingers and toes, which are often considerably distorted by it; and when, as sometimes happens, it extends to the larger joints also, it is diffi-

cult to imagine any thing more helpless than the subject of such disease ultimately becomes. Fortunately it has almost invariably a chronic character, and is attended with comparatively little pain. This is what Dr. Haygarth described, many years ago, as *nodosities* of the joints, but apparently without understanding its nature.

Another appearance which sometimes presents itself is peculiar: the surface of the cartilages of the joint seems as if sprinkled over, in spots of greater or less extent, with white powder, or smoothly painted of the same colour. When we try to scrape this off, we perceive that it is not merely superficial, but pervades the substance of the cartilage. The form of this deposit is thus considerably different from that which takes place in acute and well-marked gout, wherein it exists in small, irregular, detached portions, or as a kind of exudation which may even escape externally. But another difference, and one which would be very important if it were general, has been pointed out as existing between them. The chalk-stones, as they have been called, of gout, are well known to consist of lithate of soda; but in several cases of old synovial rheumatism which occurred to Dr. Chambers, the white deposit was found to consist of carbonate of lime. This is a curious pathological fact; but I am satisfied, nevertheless, that the difference between the deposit in such cases and in true gout, is not such as to constitute a safe ground of distinction. I have several times examined this smooth white deposit on the articular cartilages of those who have had the synovial form of rheumatism, and in all such instances it answered to the tests of lithate of soda; and on mentioning the subject to Dr. Prout, he informed me that, in the course of his experience (which we know in such cases to have been very extensive), he had never met with a deposit of carbonate of lime in the joints. I think, therefore, we may safely infer that this, though an occasional, is still but a rare occurrence.

But there is yet another change sometimes produced by this form of rheumatism—I mean suppurative disorganization of the joint in which it is situated. This is contrary to what seems to be very generally believed, and almost invariably laid down in books; but I believe, nevertheless, that it will be found, on more extended observation, to be a more frequent occurrence than has been suspected. Less, indeed, is known concerning the morbid changes which take place in the primary seats of rheumatism, than of any other portion of its history; nor is it difficult to explain

this, for very few die in the early stage of the disease; and when the patient is cut off at a more advanced period, it is in consequence of the affection of some internal organ, which either absorbs all the attention of the practitioner, or it may be, that long before the fatal event the joints have become free from the disease, as happens in the great majority of cases where the heart has been so damaged as to prove incompatible with life. Nor must I neglect to mention another circumstance—viz. that in cases which have ended in suppuration, the very fact of such termination is assumed as *ipso facto*, proving that the disease had not been rheumatism, but ordinary inflammation.

I have never seen any form of rheumatism except the synovial, in which suppuration has occurred; but of this I have seen several instances:—

A lady, about 55 years of age, of delicate constitution (residing at Chelsea), became affected with the ordinary symptoms of synovial rheumatism, affecting principally the shoulders and hips. In about a week the right shoulder joint became distended, and after a few days the articulation of the clavicle with the sternum was swollen and fluctuating. The right hip next became the chief seat of pain; and it was thought that deep-seated fluctuation, apparently from distension of the capsular ligament, could be felt. Sir Benjamin Brodie at this period saw the patient with me, and regarded it, as I had done, as a severe case of synovial rheumatism. She died at the end of a month from the commencement of the attack, without any internal organ participating in the disease, but apparently exhausted by paroxysms of fever, attended by copious perspirations. No examination was allowed; but the impression produced upon my mind at the time was, that the inflammation had run so high, as to give rise not merely to an increased secretion of synovia, but that purulent matter had been formed in the affected joints.

A man was admitted into St. George's Hospital, under my care, in 1835, affected with pain and swelling of the knees and hips. The pains next attacked the wrists and shoulders, the former of which were swollen from distension of the synovial membranes, and slightly red externally. The pain was also severe and long-continued in the left shoulder. But the chief affection from the onset consisted of severe pain in the right hip-joint, with a considerable tense elastic fulness in the groin, apparently connected with the joint. The pain and swelling of the other parts subsided in the course of a few weeks, while that of the hip joint continued.

The patient lingered for several months; and on examining the body after death, matter was found in and around the joint, with ulceration of the cartilages, and destruction of the ligaments.

Now this I regard as a case of synovial rheumatism, in which, owing to the concentration of the action on one joint, its disorganization was produced. In the first instance no doubt was entertained, or could have arisen, as to the nature of the case, its history being that of common synovial rheumatism; but had the patient not been seen till the successive affection of one or more joints had passed away, while that of the hip alone remained, the case might have been regarded merely as one of common disease of the hip-joint unconnected with rheumatism.

A woman was brought into St. George's Hospital, who was stated to have had rheumatism of a very acute character, and was treated for that complaint by a medical practitioner at Kensington. She complained of pains in her limbs generally, but particularly in the right hand and left hip. The knuckles were swollen, the tumefaction taking the shape of the joints. The first joint of the fore-finger was especially tumefied and red. She had been ill a month, and several joints had been affected in succession. She was admitted in a moribund state, and died next day. The affected knuckle contained a tea-spoonful of thin pus, with redness of the membrane round the edge of the cartilages. The left hip-joint had a thin layer of pus infiltrating the cellular membrane, external to the capsular ligament, and within it was filled with thin pus mixed with flakes: there was redness of the capsular ligament, but no ulceration of the cartilages.

George Coombs, ætat. 31, was admitted into St. George's Hospital the 23d of November, 1836, at which time he had suffered for a month from pain in various joints. He had then, however, no pain remaining, except in the left knee, where it was still severe. There was no swelling or redness, and he could bend it without difficulty, but complained much when the limb was straightened. There was little general disturbance.

Nov. 30th.—Having exposed himself to cold, he had a rigor, followed by heat and copious acid sweating. To-day has pain in the limbs generally, but particularly in the knees and shoulders, accompanied by a good deal of fever.

By the 15th December he was much better, and especially with respect to the affection of the left knee, for which he was originally admitted; but on the 19th he had a return of pain in both knees, parti-

cularly the right, the synovial membrane of which was distended.

On the 24th the left ankle was painful and swollen, and also the left elbow, which was red externally. His pulse was 116, and his countenance anxious.

26th.—Knuckle of left middle finger swollen, with perceptible distension of the joint, and redness of the skin. The copious acid perspirations continue.

31st.—The swelling of finger and elbow very much diminished; and chief complaint now is of right knee, which continued much swollen, the tumefaction being dependent on distension of the capsular ligament, accompanied by fluctuation. The limb retained habitually in a half-bent position.

In this state he continued, with little change, till the 12th Jan., when he died.

The body was examined next day. The right knee was found to contain about half a pint of thin purulent matter, with some flocculi. The cartilages were entire, and of healthy appearance; but the synovial membrane was distended, pushed up beneath the quadriceps muscle, red, and thickened. The metacarpal joint of the finger which had suffered was next examined. The flexor tendon was softened, and seemed sodden, being deprived of its silvery lustre; the articular surfaces red, roughened, and smeared with a thin layer of pus. The left ankle, which seemed to have been third in the degree of suffering, was examined, but presented no morbid appearance beyond a little redness. Neither the pericardium nor the heart presented any morbid change, unless a slight, apparently old, thickening of the mitral valves. There were between two and three ounces of fluid in the ventricles of the brain.

Now it appears to me impossible to separate such cases as the preceding from rheumatism, unless we admit change of structure in the part affected to be in itself sufficient proof that the disease had been something else—a mode of reasoning both unphilosophical, and calculated to establish an embarrassing, and I believe imaginary distinction, between those cases in which disorganization is, and those in which it is not, the result of those affections of the joints commonly regarded as rheumatism.

Again, abundant evidence will be found in the writings of those who have attended most minutely to the changes of structure which the joints undergo, to convince us that rheumatism which becomes fixed in a part may there give rise to palpable changes of structure. The fourth case, which occurs in Sir Benjamin Brodie's work on the Joints, is conclusive on the subject:—

“Henry Payne, 30 years of age, was ad-

mitted into St. George's Hospital, under the care of Mr. Hawkins, on the 7th of October, 1829.

He had suffered formerly from repeated attacks of rheumatism.

About twelve weeks ago, after exposure to damp and cold, he was seized with inflammation in nearly all his joints. In the course of a few days, the disease in the other joints had abated; but the right knee became more painful and swollen. At the time of his admission, this knee was tender, painful, and much disended with fluid, and there was a good deal of febrile excitement of the system.

Blood was taken from the neighbourhood of the knee by cupping; and this was followed by the application of blisters. The *vinum colchici*, and afterwards colomel, combined with opium, were administered internally. Under this treatment the pain and swelling of the knee subsided.

On the 27th of October he was attacked with severe inflammation of the fauces and larynx; which, however, soon yielded to the remedies employed.

On the 31st he complained of severe pain in the right side, with great difficulty of breathing; and on the 3d of November he died.

On examining the body after death, the pleurae were found inflamed, and incrustated with lymph, and serum had been effused into that of the right side. The lungs, also, were inflamed, and some portions of them were in a state of gangrene. The heart was affected with hypertrophy, and the pericardium was inflamed, with flakes of lymph adhering to it. The synovial membrane of the right knee was full of a dark-coloured fluid; not purulent, but having the appearance of a thick synovia, tinged with blood. The synovial membrane was every where of a red colour, as if stained by this secretion, and the cartilages of the joint had the appearance of having been stained in the same manner. There were some small extravasations of blood in the cellular membrane external to the joint."

But I find also unequivocal evidence of the same general nature in the works of some of the continental writers. Thus, so long ago as the time of Stoll, the occasional termination of rheumatism in suppuration of the joints, seem to have been known. Indeed, he expressly says, "in some patients these cases of rheumatism, after having caused great suffering, give rise to suppuration;" unfortunately, he does not inform us as to whether he had examined the joints after death, — but adds, a little farther on, "I treated two young girls, one of whom had the hand, and the other

the foot, affected with this kind of rheumatism. All my efforts, though they were varied and long-continued, were unable to overcome the obstinate character of the malady*."

M. Bouillaud, who strongly advocates the idea of rheumatism being analogous in its effects to other inflammations, states that he has seen three cases of the disease ending in suppuration of the joints; but in these there existed inflammation of some of the veins, and as we know that phlebitis is frequently productive of deposits of matter in the joints and elsewhere, I am not disposed to attach so much importance to his observations as to those of some others, particularly of M. Chomel. This distinguished physician maintains that rheumatism is not a true inflammation, and consequently his facts are not open to the suspicion of any bias in favour of the doctrine for which I argue. Now, in his Essay on Rheumatism, he relates the case of a patient who died at La Charité; both shoulders had been in succession the seat of acute pain, with tumefaction; and on examination after death, a purulent effusion was found in the affected joints. But that the previous history of this case had been that of rheumatism is proved by this—that Chomel asks in reference to it, whether it can be that *rheumatism* should have its seat in the synovial membranes? He then goes on to state, that in two other patients whom he had seen at the Hôtel Dieu, several joints of different limbs became painful and swollen, so that they could not perform their movements. The patients died, when increased redness of the synovial membranes, with effusion of pus, was found in the articulations alluded to. The inference which he deduces is not, as we might have expected, that rheumatism may produce these organic changes, but that inflammation of the synovial membranes may very much resemble that disease. This, and numerous other passages in the works of modern French writers, shew that they are not aware of the great distinction between synovial and common fibrous rheumatism, their reasoning being almost exclusively applicable to the latter.

In the Journal Hebdomadaire for April 1834, is the following case: — Thérèse Vellamé, aged 27, a cook, in the eighth month of her pregnancy, was exposed to wet and to the vicissitudes of the atmosphere, and experienced on the 27th of January an attack of pain in the loins, with shivering. The knees, feet, and wrists, were successively affected, and she was admitted on the 1st of February, under the care of M. Piorry. There was

* Practice of Medicine, vol. iii.

then swelling, with heat and redness of almost all the joints, and *hydarthrosis* of the left knee. She was ordered to be bled on several successive days, but two venesections only (through mistake or negligence) were practised, and those with an interval of several days. The patient remained, with little change, till the 6th of March, when she was put to bed of a dead child; she herself expired on the 9th, symptoms of peritonitis having previously declared themselves. The left knee presented externally a marked degree of swelling. On opening the joint, a considerable quantity of pus was evacuated. The cartilages were softened, and the fibro-cartilages at some points destroyed. The synovial capsule was of a deep red colour, with lymph deposited on its surface. Both ankles presented analogous appearances, but in a less degree.

In referring to the four fatal cases I have myself seen, and in analysing the others which I have adduced, I find that, in all the affection had apparently originated in the synovial membranes, evinced by pain of the joint, accompanied by a swelling, the shape, (and for the most, the fluctuation also) of which indicated it to depend upon effusion within the capsule; that at first the pains had been more or less erratic, implicating several joints simultaneously, or in rather rapid succession; but that either from the commencement some one or two articulations had suffered more than the rest, or that after a time the pain and swelling had become, as it were, fixed in certain joints, and continued there after the others had got well. As might be expected, the joints on which the force of the disease was thus concentrated, were those in which the destructive effects of the inflammation were most conspicuous.

The phenomena here are strikingly different from those which occur in rheumatism affecting the ligamentous textures; for in this last, as we have seen, however considerable the external appearances of inflammation, yet the joint internally may present on examination not a single trace by which its presence can be recognised.

It seems clear, from the considerations already offered, that the form of rheumatism which more especially attacks the synovial membranes has a greater tendency than the preceding to produce disorganization in the primary seat of the disease. This might, perhaps, be explained by the fact that the internal lining of the joints is, under ordinary circumstances, more prone to change of structure than the common ligamentous textures. There is, however, another important point to be taken into the ac-

count—namely, that the synovial form of rheumatism is more connected with a cachectic or other morbid condition of the general system. It conspicuously occurs in persons who are of feeble and debilitated constitution; or if it appear in the more robust, it is generally after some considerable and continued source of mental or bodily exhaustion. Thus it may supervene upon a long journey in cold weather—upon severe study, or acute distress, particularly when to these are superadded causes productive of ordinary rheumatism, such as sitting up during the night by a sick bed, or in the accomplishment of some trying intellectual task.

Again, the evidence of a morbid condition is sometimes yet more unequivocal, as where we see the attack supervening upon, or alternating with, gonorrhœa—an event by no means very uncommon, and presenting one of the most obstinate forms of the disease. It also is met with in connexion with other venereal affections; but as this occurs almost exclusively where long-continued courses of mercury have been adopted, there is reason to suspect that the remedy is in this respect as much to blame as the syphilitic disease.

The first indication of this form of rheumatism generally consists in a dull aching and stiffness of certain joints, particularly those which are most superficial. After a time the pain becomes of a more acute or burning character, and the parts begin to swell, the swelling presenting a model of the synovial or bursal cavity, into which the effusion has taken place: the suffering is increased either by stretching the parts much, or by corrugating them, and hence a semi-flexed position of the joint is the one usually assumed in severe cases. Motion aggravates the pain, particularly after rest of some continuance, as in the morning, at which time there is often a great deal of stiffness about the parts; but after a little exercise this subsides, and the limb assumes more of its wonted suppleness.

In the most acute cases there is smart fever, and some redness about the joints; but much more usually there is no external discoloration, and little fever; that is to say, the fever is inconsiderable as compared to that which attends the ligamentous form of rheumatism. When fever is present to a considerable extent, it generally presents the remittent type, with copious acid perspirations; and I have seen a pulverulent deposit on the skin which admitted of being scraped off, in quantity minute indeed, but sufficient to admit of being tested, and which was found to consist of the lithate of soda. Where the fever runs rather high the tongue becomes foul, and the bowels

constipated; but there is much less disposition to these states than in common rheumatic fever. Indeed, of the secretions, the perspiration and urine are those most uniformly affected, the latter being loaded with the lithates, and sometimes producing a sense of scalding as it is voided. In one case, which lately occurred to me, this was attended with slight discharge from the urethra, although I have the strongest reason to be assured that there was no gonorrhoeal affection. This phenomenon would seem to bring still more close the connexion between the urethra and synovial membranes.

The course of this disease is altogether considerably different from that of rheumatic fever; it more speedily becomes mitigated in severity when both are treated in the ordinary manner, or when both are left to the unaided efforts of nature. But it is rarely if ever cut short at once, and the subacute, or chronic condition, is much more enduring. In a first attack, perhaps six weeks may be stated to be the average duration of the illness, and in such case little, or perhaps no perceptible damage may have been done to the affected joints. But it is very apt to recur, and with each relapse its obstinacy seems to increase, and, in fact, the inflammation acting repeatedly on textures already diseased, at length may be said never to be wholly absent, giving rise to permanent swelling and stiffness about the joints, constituting the "nodosities," already described. Sometimes, after years of suffering, a truce is at length entered into, and the patient enjoys a long respite, without our art having any apparent share in the favourable change.

When the superficial joints are affected with this form of rheumatism, it is generally very easily recognised; but when it attacks those which are deep-seated and most covered, considerable difficulty may exist: for instance, with respect to the hip joint. In such cases there is usually some external part implicated, which gives us a clue to the mystery. Thus, if the great toe, or knee, or but a single knuckle be simultaneously affected, we may infer that the nature of the deep and concealed disease is the same as that of the superficial. But sometimes the *joints* are all free, and some deep-seated *bursa* is alone affected. If in an individual who has been subject to this form of rheumatism, or even without this, if he has been exposed to causes likely to have produced it, should he complain of pain accompanied by stiffness, and much aggravated by motion, with some perceptible fulness, but without heat or much constitutional disturbance, such case will frequently be found to depend upon rheumatic inflammation, with effusion into

some deep-seated bursa; at least, such cases will frequently get well under the use of those remedies which are of most avail in less equivocal examples of synovial rheumatism.

of London and Edinburgh, &c.

PART II.

To the Editor of the Medical Gazette.

Sir,

THE positions which, as far as I am capable of judging, are established by the experiments referred to in a paper published in the last number of the *MEDICAL GAZETTE* are, that besides the nerves of sensation and motion, there is a third set, the ganglionic nerves, the functions of which have not been understood, but which differ as essentially from the function of either of those sets of nerves, as their functions do from each other; that the functions of this class of nerves are to combine and convey an influence prepared by the brain and spinal marrow, and not by any particular part, but the whole of those organs, from the uppermost surfaces of the brain and cerebellum to the lowest portion of the spinal marrow, for the purpose of maintaining and regulating the functions of all vital organs, with the exception of those, the function of which depends simply on that of the muscular fibre—namely, the heart and blood-vessels; which organs, although deriving their power from a source wholly independent of the influence conveyed by the ganglionic nerves, are nevertheless placed under its immediate control*.

* We have reason to believe from many facts recapitulated in the *Philosophical Transactions* of last year, and republished, with some additions, in the numbers of the *MEDICAL GAZETTE* for the 18th and 25th of March last, that the ganglionic nerves possess no power of bestowing sen-

Thus it is that this influence, constituting the leading power in the vital system, that power to which all its other powers are subordinate, holds under its dominion every part concerned in the vital functions, whether it derives its power from another source, or from itself; on which therefore depends the formation and well-being of all our organs; and we cannot help observing with what care nature protects both the organs by which it is prepared, and those which convey it. The brain and spinal marrow are in all their parts defended by powerful bones; and the ganglionic nerves, in every instance, placed so deeply in

sibility on the parts to which they are supplied, and consequently, that those parts derive their sensibility from the same class of nerves which bestow it on other parts; nerves belonging to this class accompanying and being bound up in the same sheath with the ganglionic, as they are found to be with the nerves of motion. At first view it appeared to me probable that in those instances where the ganglionic nerves excite the muscular fibre, they were bound up with the same class of nerves which excite the muscles of voluntary motion. But there are several circumstances which seem to point out, and others which prove, that the ganglionic nerves themselves possess the power of exciting the muscular fibre. In the organs supplied by the ganglionic nerves, it is not excited in the same way as in the muscles of voluntary motion; the excitement of the muscles of involuntary motion neither being under the influence of the will nor capable of being produced, as in the case of the muscles of voluntary motion, by mechanically stimulating the nerves either of the living or newly dead animal, a fact which we have seen misled Haller in his inference respecting the relation which the nervous system bears to the muscles of involuntary motion. But the facts which leave no room to doubt that the ganglionic nerves possess the power, under certain circumstances, of exciting the muscular fibre, are, that the muscles of involuntary motion, although they cannot be excited by stimulants applied to their nerves, either in the living or newly-dead animal, can in both be excited by stimulants applied to any part of either the brain or spinal marrow; while the muscles of voluntary motion only obey stimulants applied to the particular parts of those organs from which their nerves arise: and while the muscles of involuntary motion are more powerfully excited by chemical than mechanical stimulants, the former of which, if we except electricity, have little effect in exciting the muscles of voluntary motion (my *Experimental Inquiry into the Laws of the Vital Organs*, Part II.); and lastly, we know from direct experiment, that the influence conveyed by the ganglionic nerves is the same as that conveyed by other nerves of motion, although wholly of a different nature from that conveyed by the nerves of sensation (*Philosophical Transactions* for 1836.) The most ready test, as I have elsewhere pointed out, by which we may determine whether any particular function depends on the ganglionic nerves, where the parts are too minute for the labours of the anatomist, is its being subject to all parts of the brain and spinal marrow, these being the only nerves which convey the influence of all parts of these organs. It was thus that the blood-vessels were proved to be supplied by ganglionic nerves, even to their minute ramifications. (*Philosophical Transactions*.)

the softer parts of our frame, as to be almost as well defended as if they also had been secured by bony cases.

WE are now to inquire into the nature of the morbid states of the influence conveyed by the ganglionic nerves, with a view to the improvement of the practical department of our profession; for it is impossible to conceive that a knowledge of, as far as life is concerned, the most important functions of the brain and spinal marrow; and of the only functions of the ganglionic nerves, functions of no less importance, those of combining and conveying the influence of the vital organs of the brain and spinal marrow, should not essentially influence that department: that the state of the leading power of the vital system should not be essentially concerned in its diseases.

As this is one of those powers of which the living animal partakes in common with inanimate nature, it cannot of course be subject to change by disease, but the organs which supply, and those which convey it, are as much so as other parts of our frame, and its effects must be regulated by the state of those organs.

Certain stages of their diseased states are familiar to every practical physician. But as we have neither been aware that the brain and spinal marrow supply, and the ganglionic nerves convey, the power which regulates the functions of life, our knowledge of the nature and immediate cause of many of those diseases has been extremely imperfect. From this defect of knowledge, and the want of sensibility in the parts concerned*, their early stages often excite little attention: and it not unfrequently happens that no serious attempt is made

* Neither the brain nor spinal marrow appear to possess any sensibility. Previous to our being aware of the distinction between the nerves of sensation and those of motion, certain parts of them appeared to possess sensibility, because the muscles of voluntary motion are thrown into contraction by irritating those parts. This we now know does not necessarily imply that those parts are endowed with sensibility. It is also a fact that many of the other vital organs are ill-supplied with nerves of sensation—the lungs, the heart, the liver, &c. These causes have greatly contributed to the obscurity of the diseases depending on a failure or irregular supply of the influence they convey. This may, at first view, appear to be a defect in the constitution of our bodies: but it is probably the cause of much less inconvenience than would have arisen from a high degree of sensibility in organs, the functions of which are constant and subject to frequent, and often sudden, causes of excitement.

to arrest their progress, till it has been such as to defy all our means.

Nothing can be more evident than the inference that if the organs of the leading power in the maintenance of the functions on which the healthy structure of every part depends, be distributed throughout every part of the brain and spinal marrow, those functions must be influenced by all causes which tend to impair the vigour of either, or any considerable portion of either of these organs; and no fact can be more notorious than that, in many of those instances where the nervous system has long suffered under causes of irritation, derangement of function in some organ essential to life is often at length established, which frequently resists the usual means, and terminates in a fatal derangement of structure; while in the earlier stages, from the insensibility of the vital organs, the patient's state appears to differ but little from that of others who are what is called nervous, and often continue so for a long life without any symptoms of danger supervening.

It is evident that these cases, however similar in their symptoms, must be of an essentially different nature.

The nature of the difference will be evident if we compare them with the facts detailed in the paper so frequently referred to in my last communication, on the Powers of Life, in the Philosophical Transactions for 1836. In the one case, the derangement has its seat in the central organs of the sensitive system; in which, therefore, however severe the suffering, life is not endangered, because the organs of the sensitive system have no share in maintaining it: in the other, it extends to the vital organs of the brain and spinal marrow; and the cause of the two cases bearing so near a resemblance to each other, arises from the sufferings being in both in the sensitive system; for the one system, for the reasons stated in the paper just referred to, never suffers without the other more or less partaking of the suffering; and all our feelings belonging to the sensitive system, the sufferings are nearly the same, whether the vital organs of the brain and spinal marrow partake of the disease or not: indeed, often less in the former case, as might be supposed, when the original disease is in the insensible parts of our frame; until the evil declares itself by the suf-

fering of some other part of the vital system, more or less supplied with nerves of sensation, and the functions of which consequently being more evident, have been better understood.

The first thing which suggests that the disease may not be wholly confined to the sensitive system, is the functions of this part being more prominently and constantly affected than is common for those of any particular organ to be, in what we call nervous complaints.

Even under such circumstances, however, we are not always alarmed; we have often before seen such affections of the same part arising from causes, the effects of which proved trivial, and yielded readily to the usual remedies; and, not being aware of the change which has been gradually going on in the vital organs of the brain and spinal marrow, we see no reason why the derangement of function should not yield as in other cases; the cough, or the headache, is a little more obstinate than usual, but we see no reason why the patient should not do well.

In such cases, however, unless we can trace the source of the disease, and remove the cause which is preying on the vital organs of the brain and spinal marrow, we generally find that he does not do well; and are at length awakened to his real state, by symptoms of change of structure supervening on those of deranged function, when, for the most part, the disease has advanced too far to be arrested.

Cases of this description are of two kinds. I have just had occasion to refer to a paper in which are detailed the various causes which maintain a powerful bond of union between the sensitive and vital systems; in consequence of which, it never happens that the central organs of the one are much affected without those of the other more or less partaking of their affection. Their vicinity alone, indeed, is sufficient to produce this effect, for there is no exception to the law which I have elsewhere considered at length*, that all neighbouring parts sympathise.

The degree in which this sympathetic affection of the central parts of either system tends to produce disease in the other organs of that system, depends not

* Gulstonian Lectures, delivered before the College of Physicians in 1835, and published in the same year.

merely on the degree in which its central parts are affected, but in a great degree on the liability to disease in other organs; and therefore on the particular constitution of the patient; which also determines the organ which will suffer most, unless some particular organ has been weakened by accidental causes, such as having suffered by previous disease; for the chief effect of the derangement, which influences the whole, will always fall on the weakest part; and it is a law of our frame, which I have had frequent occasion to illustrate, that the morbid affection of any one part being established, tends to divert the cause from all others.

Thus it is, that whether an organ, secondarily affected, belong to the sensitive or vital system, the cause may either originate in the other system, or it may be the effect of causes directly injuring the central parts of the system to which the organ in question belongs. Both cases, it is evident, are very different in their nature from those in which the cause of injury acts directly on this organ itself: these are simple cases, of which I do not speak, and in which both the cause of the disease and its treatment are well understood. Thus, on the one hand, we see cases in which the long continuance of the depressing passions, what is called a settled grief, for example, gradually impairs the vigour of the central organs of the sensitive system; by degrees those of the vital system partaking of this debility; and in consequence of this secondary affection, the function of some organ belonging to the latter system is deranged; and the derangement, if the cause continue to operate, maintained, till it terminates, as almost always sooner or later happens, in such derangement of structure, that the organ is no longer capable of any degree of its healthy function, and a fatal termination ensues.

On the other hand, we see such causes of injury as directly debilitate the central organs of the vital system, produce the same train of symptoms, except that they are not preceded by the affections of the sensitive system, which in the foregoing case lay the foundation of all that follows.

With respect to this case little need be said. The safety of the patient depends on removing the cause of derangement in the sensitive system, which, from the sensibility of the parts concerned, is generally sufficiently evident, before the

structure of some organ essential to life, in consequence of the central organs of the vital system partaking of the diseased state of those of the sensitive system, is seriously deranged; for after this has taken place, our means, although they may in some degree retard, can rarely prevent the fatal termination.

The object of this paper is to direct the attention of the physician to the former case, in which the cause of disease, in consequence of the insensibility of the organs of life belonging to the brain and spinal marrow, and many of the other vital organs being ill supplied with nerves of sensation, not unfrequently makes its advances in so insidious a manner, that, as we have just seen, the symptoms of derangement of structure in some organ essential to life is often the first thing which warns the physician of his patient's danger.

The only means of preventing such a result is to observe with care the states which precede it, that we may be enabled to distinguish the threatenings that should warn us of its approach; and thus learn to distinguish those cases in which the vital organ of the brain and spinal marrow are suffering in such a way as may sooner or later incapacitate them for maintaining the functions on which life depends.

The subject naturally divides itself into three parts: in the first place, to determine the nature of the immediate cause of the disease—the state of the organs from which it immediately arises; secondly, the remote causes—the causes which produce that state of the organs in question; and lastly, the means best calculated to obviate their effects. The first I shall consider in the remaining part of the present paper, reserving the second and third, with which the subject will close, for my next communication.

It appears from a paper to which I have had frequent occasion to refer, because it contains a recapitulation of all the more important facts relating to the subject*, that the leading power in each of the two systems, under which all the powers of the living animal arrange themselves, both influences every part, and is influenced by every part, of the

* Philosophical Transactions for 1836; and Medical Gazette for March 18 and 25, 1837.

system to which it belongs. This power, therefore, suffers by every cause of injury going on in any part of that system, all the functions of which depend upon it. I have already stated my reason for confining my attention to causes directly operating on the leading power of the vital system; namely, that when the affection of the sensitive system is such as, in consequence of the sympathy which exists between the central parts of the two systems, to injure the organs of the leading power of the vital system, the cause must, from the sensibility of every part of the sensitive system, always be such as to be evident to the most careless observer.

In the cases to which I wish to direct the reader's attention, on the contrary, the little sensibility of the parts concerned, from the vital organs of the brain and spinal marrow being devoid of sensibility, many of the other vital organs but ill supplied with nerves of sensation, and the cause in general operating slowly, the symptoms are often such, in the early stages, as appear to indicate no serious consequences; in general differing but little from those of what are called nervous complaints, which are, for the most part, free from any risk to life.

But it will easily be believed, that if a cause tending to debilitate the organs of the leading power in the vital system, however feeble, be long continued, its continuance compensating for the feebleness of the impression, these organs may so suffer as to interfere with the due preparation of the influence they supply, on which we know from direct experiment the functions of all vital organs depend. The apparent inadequacy of the cause, in the majority of cases, is a chief source of danger; for we shall find, that when the cause and its tendency are detected at an early period, its effects may almost always be obviated. As the central organs of the vital system feel the effects of all causes operating on any part of this system, such causes, it is evident, must operate most frequently, as well as powerfully, in those parts of the vital system which are most extensive, and most exposed to causes of injury.

Now the vital organs to which these observations in the greatest degree apply, are the alimentary canal and its appendages; and so habitual are causes of irritation in them, and so many of them

such as we find are unattended with any serious effects, that of all such causes, they are least calculated to excite alarm. We are accustomed to see them recur for a great length of time without producing any serious effects on the general health.

In some cases, however, in affections of these or other vital organs, the patient perceives that a sense of debility in some, in others what is called a fret of the nerves, which have only been temporary, becomes more permanent, and at length constant. Under such circumstances he soon feels his strength more or less permanently impaired; but the first thing which generally makes him anxious respecting his complaints, is finding that he is not equal to his usual mental efforts, for the sympathy which exists between the two systems is mutual. As affections of the sensitive at length influence the vital, those of the vital seldom fail more or less to influence the sensitive system.

In affections of the alimentary canal, however, a more direct cause is at the same time operating. This canal is one of the few vital organs copiously supplied with nerves of sensation, and consequently its affections directly, and to a great degree, impress the central organs of the sensitive system, and that to a much greater degree than happens with respect to those of any other vital organ; so that by causes of irritation in that canal, the central organs of the vital system are doubly assailed, by the direct effect on these organs of all impressions made on any vital organ, and by their immediate sympathy with the central organs of the sensitive system, which is but little influenced by the affection of the vital organs ill supplied with nerves of sensation.

Now as soon as this sense of debility or fret of the nerves becomes continued, there is a cause operating, which is constantly tending to debilitate the organs of the leading power of the vital system; and however slow its progress and little prominent its symptoms, in consequence of the vital organs of both the brain and spinal marrow being devoid of sensibility, its ultimate effects may be fatal; and it appears from experiments referred to in my last communication that they may be so, before the general debility of these organs is such as even to approach a total loss of power, because any considerable diminution of

the influence they supply was found sufficient not only to destroy the function, but even structure of other vital organs.

Life, therefore, must cease from this cause, before the functional disease of the central vital organs can approach that stage at which change of structure takes place in them. Wherever, therefore, change of structure in these organs is observed on inspection after death, their disease must have been partial, and such as originated in the part affected. Such a result cannot take place from a cause operating generally on the central organs, which all disease of other vital organs must do, as each is not only under the dominion of, but capable of influencing, the vital organs in every part of the brain and spinal marrow.

If any of those other organs happen, under such circumstances, either from peculiarity of constitution, previous disease, or other cause, to be more liable to disease than the rest; the cause which operates on all will on it make its chief impression: and according to a law of the animal frame to which I have had occasion to refer, when disease is established in one part, the effects of the cause are diverted from others; and then the functional disease—for in such cases the first deviation is only functional—if the cause be allowed to continue, is sooner or later, and in some cases rapidly, succeeded by disease of structure.

Such is the course of the diseases to which I am about to direct the attention of the reader. Their course is variously modified in different cases. The limits of the present papers do not permit of an attempt to enumerate all their modifications. I shall only mention a few of the more important, which cause the derangement in different cases to assume so different a form, that it is difficult to refer them to the same class of diseases.

In other essential respects, besides that just mentioned, diseases of this description are powerfully modified by peculiarity of constitution. In some, the vital organs of the brain and spinal marrow resist disease much more powerfully than in others. In others, the other vital organs are less than usually liable to disease. In the former, the debility or fret of nerves does not readily become permanent, for their permanence

seems always to depend on some affection, that is, some degree of debility, more or less, having taken place in the central organs of the vital system. In the latter, although their permanency is established, the other vital organs resist their effects on the central organs more powerfully than usual. The disease, from this cause is, as it were, arrested in its progress; the power of the central organs is impaired, but the organs which depend upon them feel less than usual slight diminutions of the nervous influence; and thus the functions of life going on, the state of the central organs themselves is better maintained than is usual under such circumstances.

In some, the affections of the central organs of the vital system affect the sensitive system in one way, in others in another; and often so differently, that the two cases appear to have nothing in common. One patient appears only languid, and what is called out of health. In others, the sense of languor and debility is extreme, or restlessness, and a painful sense of oppression, characterize the disease. In not a few, the leading symptom is a frequent recurrence of severe and sometimes agonizing muscular pains, not unfrequently even producing delirium.

It is a remarkable fact, that all such severe affections of the sensitive system, however tormenting, seem generally to be a means of safety, by diverting the tendency of the disease from more vital parts. I have uniformly found that in such cases, many of which I have seen, the organs of the vital system are less apt to suffer than where the disturbance of the sensitive system forms a less prominent part of the disease, and where consequently it attracts less attention.

The most deceitful of all this class of diseases are those in which the disease does not arise from irritation in distant parts, but originates in the vital organs of the brain or spinal marrow themselves. From the insensibility of these organs, the affections which originate in them are detected with much difficulty; and are often overlooked till they have made great progress, and even hardly betray themselves by any symptoms but those which attend the more common nervous derangements; their chief characteristic being the uniformity with which they advance to a fatal ter-

mination. In my *Gulstonian Lectures*, I have endeavoured to point out their diagnostic and illustrate their nature, by an account of two post-mortem examinations, compared with a detail of the symptoms.

When we consider the sympathy which exists between the organs of the leading powers in the sensitive and vital systems, and that the former are the source of all our feelings, while the latter appear to be wholly insensible, we cannot be surprised at the endless variety and striking dissimilarity of the affections of either, often depending as much on causes which influence the sympathy which exists between them, as on the morbid condition of the one originally affected.

It is hardly necessary to observe, that the symptoms which may arise from affections of these two sets of organs—the centres of the systems which regulate the whole of the functions of our complicated frame—must necessarily be of infinite variety; and when we take into account the powerful sympathy which exists between them, it is evident that the affection of either may produce, in different constitutions, almost every variety of affection of which our organs are capable.

My chief object, however, is to direct the attention to those cases the obscurity of which has produced the most fatal effects; and which may be obviated by a better understanding of their early and curable stages, which are marked by no prominent symptom; and sometimes by no regular set of symptoms belonging to the affection of any particular organ; because the symptoms which arise from disease in either set of central organs, or even both sets, when a diseased state of no other organ has supervened, so that certain parts of them remain the only seat of the disease, must, from their insensibility and the nature of the functions of both, be general, not local symptoms.

However varied the other phenomena in all the cases I now speak of, the diagnostic symptom of their earlier stages is still the same; a continued general debility or fret of nerves, without the symptoms which indicate a fixed disease in any particular organ, with the exception of those, by far the most common, in which the state of the central organs is the secondary disease, the affection of another part having pro-

duced it. The characteristic symptoms which arise from a diseased state of either set of the central organs, being, from their nature, necessarily general not local symptoms, greatly contribute to the obscurity of their early stages. But in most cases the disease gradually assumes a different form.

The functions of some other vital organ, we have seen, beside that, the disordered function of which had produced the general affection, begins particularly to suffer, in consequence of the failure of function in the central organs of the vital system. This almost always happens where the original affection is in an organ little inclined to change of structure, and the affection of which consequently long supports the irritation without proving fatal. When this change takes place, except the disease has arisen from an original affection of the central organs themselves, which is comparatively rare, it consists of three distinct affections; the disease of the vital organ in which the whole originated, the disease of the central organs of the vital system produced by it, and that of the organ, the affection of which arises from the affection of the central organs.

In addition to these, the essential symptoms of such cases, there are always more or less of two other trains of symptoms, having their origin in the central organs of the sensitive system, which are directly influenced by the disease of the part originally affected, more or less, according to the sensibility of that part; and sympathetically, by the affection of the central organs of the vital system.

Now the obscurity, and consequently the danger, of the early stages of such complicated, but we shall find very common cases, depending on the vital organ originally affected being ill supplied with nerves of sensation, and the insensibility of the central organs, often causing the affections of both to be overlooked; the first thing in general, as appears from what has been said, which commands serious attention, is the affection of the vital organ secondarily affected through the central organs of the system to which it belongs. And as the attention of the physician is often not attracted to the original affection, in consequence of the little sensibility of the organ in which it is seated, or is not aware of its connexion with the state

of the organ secondarily affected, which is generally the most prominent part of the disease, he is not prepared to find the latter either more obstinate and more apt to run to change of structure than the same affection of the same part when it is the only disease.

The means of preventing the fatal result are the discovery and removal of the original disease which caused and supports the diseased function of the central organs, and without which the cure of the secondary disease is impossible.

In one case of this kind, post-mortem dissections have directed our attention to the original disease, although its mode of operation has not been understood. I mean in the hydrocephalus internus; and what has been the consequence? That in that which was previously an almost uniformly fatal disease, now that dissection has proved that it derives its origin from diseased function of the liver, the proper treatment is so successful, that there are few serious diseases in which our practice is more uniformly efficient; and it will appear from what I am about to say in my next communication, that an equal improvement in the prognostic has already taken place in other cases, of a nature quite as important, in consequence of the application of the foregoing principles.

One observation applies to all such complicated cases; however little annoying to the patient, or formidable in the view of the bystanders, both of which generally arise less from the degree of the derangement than the insensibility of the organs affected, and however slow its progress, the case will certainly sooner or later prove fatal, if the cause which has induced and supports the debility or general fret of nerves (which, in its turn, is the cause of debility in the organs of the leading power of the vital system, and this of the disease which last supervenes on which the danger depends,) cannot be discovered and removed; for no disease can yield if the cause which produces it continues to operate.

It is therefore the original disease, however unobtrusive its symptoms, to which must be ascribed all that follows, and on the removal of which the safety of the patient wholly depends.

In the remaining communication I

shall consider the remote causes, those causes which tend to produce a debilitated state of the vital organs of the brain and spinal marrow, the immediate cause of the more prominent disease; the means of removing them, and as far as it has taken place, counteracting their effect.—I am, sir,

Your obedient servant,

A. P. W. PHILIP.

Cavendish-Square,
Nov. 13. 1837.

SOME ACCOUNT OF MESMERISM.

A Monsieur l'éditeur de la Gazette Médicale.

MONSIEUR,

QUELLES que soient vos opinions sur la science que je professe, que cette science soit ou non fondée, elle a maintenant trop de partisans pour ne pas être examinée avec attention. J'attends donc de votre impartialité que vous ne vous refuserez pas à l'insertion dans votre journal de quelques articles propres à faire connoître la découverte de Mesmer, et les travaux des hommes distingués qui s'en sont occupé.

Cette preuve honorable de votre esprit de justice, me permettra peut-être de faire cesser les préventions qui existent contre le Mesmérisme, et de préparer les esprits à un nouvel examen.

J'ai l'honneur de vous saluer,

BARON DU POTET DE SENNEVOY.

Londres, le 11 Novembre, 1837,
25, Orchard-street, Portman Square,

Anthony Mesmer, to whom we owe the discovery of animal magnetism, was born at Vienna, in the year 1740. He received his degree as Doctor of Medicine, from the faculty in that city, in 1766. His inaugural thesis is entitled, "On the Influence of the Planets upon the Human Body."

Led by the nature of his mind to deviate from the beaten track, and aware of the little certainty of his art, he was anxious to establish it upon incontrovertible principles. The yearning after truth took possession of his spirit; he followed up the search with enthusiasm: but a just idea of the character of Mesmer could perhaps only be given by quoting what he himself wrote, when most absorbed by his discovery.

It would be difficult to say how

Mesmer arrived at the detection of that agent with the study of which we are now occupied. Whether it was by the force of his own genius, or that he had read the authors who long before him had treated of this matter, is of little importance to us. However that may be, Mesmer is entitled to our utmost gratitude for having recalled our minds to the study of magnetism.

The doctrine of Mesmer first began to be practically applied towards the year 1775, about which time he published a portion of his system.

The principles of Mesmer were not fundamentally so different from those of other physicians as might be imagined. Mesmer thought that every motion of the body, external and internal, whether in health or disease, takes place by the agency of the nerves. Now this opinion of Mesmer was held by all other physicians. Mesmer thought that the action of the nerves itself depended on the action of a very subtle fluid; so thought all other physicians. Mesmer thought this fluid to be itself subject to various agents, some of which (such as the bodies by which we are surrounded) are external; and others (such as the various affections of our mind, our will, our passions, the organization of our frame, &c.) are internal; all other physicians thought the same. Mesmer thought that the normal state of our functions, on which health depends, is maintained by the regular action of the nerves; other physicians thought so too.

Mesmer believed that the cure of diseases is effected by crises; other physicians also considered this to be the case.

In what, then, did Mesmer differ from the physicians of his age? In this: Mesmer thought that he had discovered the secret of directing at will, and by very easy means, the fluid which sets our nerves in action, and thereby of imparting to them such action as might be requisite either for the preservation of health or for the cure of disease. Mesmer, in fact, laid claim to having arrived at a better knowledge of the laws of life than the physicians who had preceded him. It was this which they disputed.

His ideas were not favourably received. He was repulsed on all sides, although he had treated some patients by magnetism, and had obtained the most complete success. After having been exposed to several disgraceful

scenes, he quitted Vienna in the year 1777, thinking he had done enough for his ungrateful fellow citizens, and bearing with him the hope that the day would come when they would do him justice.

A few years only from this period had elapsed, when that which was denominated Mesmer's discovery was already producing the most vivid sensation amongst the neighbouring nations; and when he arrived in Paris, in 1778, preceded by his reputation, he found himself the object of public attention.

It was not long before he associated himself with the most distinguished medical men of the capital, and more particularly with Dr. Deslong, first physician to the Comte d'Artois. An eager desire was manifested on all sides to assure Mesmer that he would be more successful in France than in his native country, and he was persuaded to lay his system before the Academy of Science.

Unfavourably received by this Academy, the ideas of Mesmer met with no better success at the Société de Médecine. Notwithstanding this failure, however, the frankness and good faith of his proceedings obtained for him the good will of many medical men, who zealously devoted themselves to the practice of magnetism, and published its successful results in all directions.

Treated without consideration, I might say almost ignominiously, by the learned societies, Mesmer was, nevertheless, eagerly sought after by a great number of distinguished persons. This circumstance suggested to him the idea of opening an establishment, where patients hastened to be treated according to the new mode; and some cures which were effected there finally established his reputation.

If the first propagators of magnetism had followed the example of that ancient philosopher who contented himself with walking in the presence of one who denied motion—if they had restricted themselves to producing effects without endeavouring to account for them—the cause of magnetism would long ago have been won. But they did not follow this course. They were in too great haste to erect systems, and to bring them forward as containing all the secrets of their art. Carried away by enthusiasm, the partisans of Mesmer knew not how to set limits to their

faith; the cure of some diseases led them to believe in the possibility of curing all. They had the indiscretion to affirm in their writings that there was but one life, one health, one disease, and consequently but one remedy—and that this one remedy was magnetism.

Extending their views to the future, they thought themselves entitled to predict that the agent discovered by Mesmer would operate a considerable modification of our morals, and a complete modification of our organization.

And these promises were actually published, accompanied by reflections not less startling.

"What we have just announced," said they, "seems to savour of enthusiasm; but it will be known some day that we have been considerate towards received opinions, and that we have not done full justice to our subject."

Not less astonishing than the enthusiasm of the magnetisers was the conduct of the scientific societies, who were as incapable as they of preserving sufficient coolness to pronounce, without prejudice, their decisions respecting magnetism.

Numerous scientific committees were officially appointed by Louis XVI. to examine into the system of Mesmer. These committees included Lavoisier, Bailly, Franklin, Jussieu, and a multitude of other names not less illustrious. The public, therefore, had a right to expect every thing from such an Areopagus. There could now be no doubt that the subject would be placed in its true light; yet this did not happen. But the reader should be transported back to that period, and turn over the history of those transactions, in order to form an idea of the agitation into which France was plunged by this question of magnetism. On one side were to be seen the learned bodies, animated by party spirit, endeavouring to proscribe magnetism; on the other, courtiers and citizens warmly embracing the new doctrine, and espousing the cause of Mesmer, whose character and conduct had conciliated general esteem. The one party denied all the effects of magnetism, or explained them on erroneous grounds, which I shall hereafter relate; the other, on the contrary, adopted all that their leader had said and written, and thus carried their belief too far. The dispute was warmly

urged on both sides. Paris was deluged with publications (more than 500 appeared in the space of eighteen months;) wit and learning were alternately employed. It would be difficult, at the present day, to conceive the high pitch to which the excitement was carried, if we did not possess the most unquestionable testimonials to prove the bitterness of the two parties.

The dispute became fiercer every day, and the commissioners chose the very moment when men's minds were thus exasperated to pronounce on the question of magnetism. Their report, I regret to say, was in consequence marked throughout by prejudice; and in every part of it we may observe them resisting the truth, which they endeavour throughout to elude. All arguments are considered good by them for the explanation of facts which were then inexplicable, and they did not fear to compromise their well-earned reputation, and to leave to posterity a monument destined to commemorate the aberrations of genius when excited by passion and prejudice. Yet, notwithstanding the unfavourable reports of the Commissioners, effects continued to be produced, and to gain partisans to the new doctrine.

This circumstance reminds us that many questions have been decided without the concurrence of the learned; and often, indeed, notwithstanding their formal opposition. It is well known, that the first persons who asserted they had witnessed the fall of aerolites, found no credit for their recital; but at length similar facts were attested by others, and at this day no one disputes a phenomenon at that time denied by the most learned. What occurred respecting the aerolites will indubitably take place with animal magnetism, and the period, perhaps, is not far distant. But let us proceed with our narrative.

Intolerance is frequently allied with power. The learned societies of France, then firmly constituted, knew that they could impose, with impunity, their belief or their opinion on the public. They were also not ignorant of the injury they could do to Mesmer, and they therefore began, previously to making their report, to persecute the followers of the new doctrine, and a great number of physicians fell victims to their zeal for the propagation of magnetism.

They even went so far as to endeavour to make these men act against their consciences. Such things would appear to us, at the present day, incredible, if they were not established by a multitude of memoirs written at the time. Let me be permitted to cite a portion of one of these, which will give some idea of the animosity which then existed against Mesmer and his adherents.

I extract the following passage from a pamphlet, entitled "Report addressed to the Public upon some abuses caused by Magnetism," by M. Douglé, Docteur regent.*

"Thirty magnetising physicians were denounced, and each of them received a special summons. They almost all appeared, and were sent into a separate chamber from the assembly. Each waited with impatience the general summons, and walked up and down, wondering what was going to happen. I was informed that it was proposed to require us to sign a kind of formulary. We will see what it contains, said I, and then we shall either sign or not, as we may think proper.

At length the usher appeared, and I was first summoned, having that honour as the eldest of the company. I entered, much surprised at not finding myself followed by any of my companions. I was requested to be seated, and the Dean began by inquiring if I had paid any thing for the instruction I had received in magnetism. Still more surprised at this question, I answered that M. Deslong did not receive money; that he only admitted medical men to observe and to assist him; that he was in the highest degree respectable, modest, and obliging; and that, moreover, the faculty were not ignorant of this. I will not weary the reader by the detail of the other questions put to me. I was interrogated like a criminal, and I fancied myself transported into the great hall of La Tourmelles. They at length concluded by presenting me a paper, which I did not consider myself at liberty to subscribe. I declined signing it, and assured the Faculty, in order to prove my zeal and deference, that I had not yet discovered in this method a sufficient degree of utility to induce me to make any report on it; that I had witnessed some results

from it, which might be attributed to the effect produced by a man in health upon an invalid; that in order to magnetise patients in their beds, much courage, strength, and health were requisite, &c. I left the chamber, and was succeeded by another."

The following is the formula which they wished every Doctor-regent* to sign:—

"No physician shall declare himself a partizan of animal magnetism, either by his writings or by his practice, under penalty of being struck off the list of Docteurs regents."

This decree bears date, April 23d, 1784.

The many truths which have been rejected and persecuted when first brought forward, and which have been since established, ought to render us more circumspect, and should deter us from denying new facts, however strange they may appear to us.

But it is not thus that we proceed. The experience of past ages is lost upon us, or, at the utmost, we only derive from it barren lessons, which are of no service to us when the opportunity of putting them in practice presents itself; for such is the constitution of our minds, that the things which appear the clearest to us when we consider them abstractedly and in a general point of view, we can no longer apply in particular cases, when we are misled by our prejudices and partialities.

I return to the sentence pronounced by the ancient Faculty against some of its members accused of believing and practising magnetism.

Several of the Doctor-regents did not submit to the judgment pronounced against them; they would not tamper with their conscience. They were inexorably erased from the list of Doctor-regents, and deprived of the honours and emoluments attached to their function. Of this number were Dr. Deslong, and Varnier, another Doctor-regent; the latter, because he manifested by his practice, and in his writings, a too obstinate adherence to the pretended animal magnetism. This decree is dated Aug. 27th, 1784. It produced a memo-

* Doctor regent was a dignity or title belonging to those distinguished physicians who at that time constituted the Academy of Medicine. These regent Doctors had the right of judging the conduct of other physicians, and of citing them to appear before them.

rial from M. Varnier, who protested against it. This memorial, drawn up by M. Fournel, an advocate, is a valuable monument of sagacity and prudence, as opposed to the irritation of the Faculty. It is accompanied by the joint opinion of seventeen of the most distinguished advocates of the time, who concurred in censuring the conduct of the Faculty, especially for exacting an oath that any individual would never believe in magnetism, and never become a follower of the system.

This act of intolerance, by a body which should have known better how to respect itself, contributed much towards increasing the number of those who favoured the new doctrine; and that which gave still greater stability to the system of Mesmer, and shook the respect still preserved by some persons for the decision of those who had judged him, was the resolution of M. Jussieu, who refused to sign the report drawn up by Mauduyt, Andry, and Caille, with whom he had been associated in the investigation. M. Jussieu made a separate report, in which, without entirely admitting the system of Mesmer, he yet seems to acknowledge that there is some foundation for it.

M. Jussieu performed an act of great courage in thus separating himself from his colleagues, and did not fear to encounter the ridicule which, in the learned world, awaited at that time all the partizans of magnetism; for notwithstanding the striking and positive proofs of its existence, Mesmer was ridiculed on the stage, burlesque poems were published against his doctrine, and himself was travestied in songs which were circulated throughout Paris. Magnetism was the subject of every conversation.

Before he left France, Mesmer visited Spa, where ill health detained him for some time. Many of his patients distinguished by rank and fortune had followed him thither, in order not to interrupt the course of his treatment. These invalids sympathised warmly in the vexation of him to whom they ascribed the relief of their sufferings. Attached to magnetism, of which they had felt the beneficial effects, they resolved to insure its diffusion in France by means of a subscription, which should provide the author of the discovery with such an independent fortune as would enable him to propagate it in the most efficient manner. This subscription did take

place. Mesmer accepted the proposal made to him to instruct pupils; and the subscribers, who were to have been limited to a hundred, much exceeded that number, although each subscription was 100 Louis. The members of this society, instructed in the doctrine of Mesmer, executed the project they had conceived; they spread the knowledge of magnetism in the provinces, and Mesmer quitted France to return no more.

[To be continued.]

ON SCURVY.

From the Annual Report of

DR. MURRAY,

Principal Medical Officer at the Cape of Good Hope, for 1835.

Communicated by Sir James McCorgor, Bart.

[Concluded from p. 259.]

V. Report of Staff Assistant-Surgeon Morgan.

Bathurst, Feb. 1837.

ALTHOUGH scorbutus has been so rife among the troops stationed in the New Province, no case of it has originated in this sub-district; therefore, whatever desire I have to investigate its causes, I have had no opportunity of doing so from actual observation.

This village was selected as a place for the reception of the scorbutic cases, towards the end of last year, on account of the pleasantness of its site, and the amenity of its climate; and also because it afforded, at the same time, facility of obtaining hospital accommodation, and vegetables, for the patients.

Thirteen cases arrived on the 16th November, eighteen on the 2d of December, six on the 4th, five on the 15th, and eleven on the 22d of the same month,—making in all 53 during 1836; and I have instituted a minute inquiry among these individuals respecting the origin and causes of the disease, of which the following is the result:—

The men of the 75th regiment appear to be the chief subjects of its attack, as no men of any other corps have come under my notice. This regiment shared, with all the other troops on the frontier, in the fatigues of the early part of the late Caffre war; but, occupying the rear line in the latter part of it, the na-

ture of their duty was different from that of the 72d regiment, and the other troops, which advanced into Cafferland against the enemy.

The duty of the 75th regiment consisted chiefly in assisting to escort supplies to the front, which was one of constant watching and considerable fatigue, as they were surrounded by lurking enemies; and when the campaign was over, and a change was allotted to them, they had still very fatiguing duties, since, in addition to that of escorting waggons, they had the building of huts and forts at their new stations; and when they got into their huts, such was the material of which they were made, and the inexperience of the workmen, that they did not afford sufficient shelter against the heat, cold, or rain.

In the next place, the meat being inferior in quality, the quantity of it eaten, from the way they were obliged to cook it, did not afford proper nourishment. They had no change of diet—no vegetables—no condiments and stimulants sufficient to excite the stomach; salt and pepper were not always to be had, and wine and spirits were only issued by starts.

As the transport of supplies passed through King William's Town to the advanced posts in the New Province, that is, to Forts Wellington, Warden, and Waterloo, and as the 75th regiment was quartered at these, great part of the escort duty, which was still necessary in time of peace, fell on it, and pressed hard on the men, so as to make them draw comparisons between themselves and others, and to render them discontented. Thus a desire of change was created; the men grumbled, and soon a languor shewed itself, which proclaimed the unhealthy diathesis that had crept into their constitutions.

In the months of December, January, and February, the weather in the part of Cafferland that was occupied by the troops is sultry, with thunder-storms; and days of great heat are often succeeded by damp and cold nights, with fogs in the valleys, and dew on the high ground.

I understand that as early as January and February (of 1836), scurvy, under the name of *purpura*, began to make its appearance at King William's Town; that it commenced at Forts Warden and Waterloo in the beginning of July; but that at Fort Wellington, the site of

which is greatly more elevated (being on the Gounbe heights), it did not become developed till a later period. The position and aspect of the several posts in the New Province differed very much; yet the disease appeared at them all, except, I believe, at Forts Beresford and Murray, where it seems to have made little if any impression; which is ascribed to the men at these having better huts, and occasionally some vegetables. At Forts White and Cox, it appeared in July or August.

I will now attempt to describe the symptoms and mode of treatment, as I have been best able to collect information; and I shall adhere to the actual accounts given by the patients.

Prior to the attention of the men themselves being particularly called to any marked symptom of the disease about them, it was observed by their officers and comrades that they fell off in flesh, and had a haggard countenance. About the same time they felt unusually fatigued after any exertion, and had an unwillingness and aversion to take duties, or any active exercise. The appetite did not appear to fail, but, on the contrary, was good; and the taking of their meals was the only thing that roused them for a time from their apathy and listlessness. They had a sense of internal heat, but no particular thirst. They felt distension of the stomach, and a sense of weight and anxiety in the precordia, especially after meals; but they had no acid eructations. They had occasionally slight pains in the back, thighs, and legs, which at first were considered to be of a rheumatic nature. They had no disposition to perspiration, but, on the contrary, a feeling of dryness and chilliness of the surface. The extremities were cold, and they were particularly sensible of the want of sufficient bedding to keep them warm, which produced restlessness in the first part of the night. The state of the bowels and urine was not remarked by them to be unnatural.

These symptoms used at first to be considered the effect of cold, and in many were so slight, that they did not require to put themselves on the sick list for a considerable time; but others were obliged to apply very soon for medical aid. After some continuance of the above premonitory symptoms, which varied in length in different individuals (*constitutions?*), spots began

to appear about the ankles and legs, and the skin assumed a blue colour, similar to that from a blow, in patches or streaks, frequently extending from the ankle to the middle of the thigh. The ankle and knee-joints swelled, and became painful, stiff, and contracted; and the skin felt like a board.

During the progress of this "*black-leg*," as they term this disease, from the discoloration being one of the most prominent and early symptoms, the gums became very tender. Some state this as the very first indication that they perceived; others as coming on at the same time with the spots on the limbs; and some say that it only appeared after the livid and swollen state of the limbs got to the worst; and it would appear, from their account, that the earlier the gums became tender and spongy, the less violent were the other symptoms; and *vice versa*.

As the disease advanced the appetite became very irregular; pain in the chest, attended with a sensation of fluttering and palpitation of the heart, which was very troublesome. The bowels were often relaxed, alternating with constipation; and the stools were dark, offensive, and sometimes contained bloody, putrid-like matter. The pain of the chest, in particular, continued a symptom of complaint to the last, causing a shortness of breath, which was most distressing on lying down. The pain was chiefly in that part of the chest crossed by the strap of the knapsack; and cough was sometimes present. In cold and damp weather the symptoms always became aggravated; and I have sometimes remarked, when convalescence was slow and tedious, that recovery was hastened by the patients being sent to resume their regular duties and employments, so soon as their strength would permit.

The treatment of most of the cases that came under my care had been previously under the direction of several different medical officers, and was very indistinctly reported to me; but I ascertained that the principal remedies exhibited had been wine, porter, spirits, vegetable acids, quinine or decoction of bark, neutral salts, especially nitre, and generous diet, with vegetables and lemons, or oranges, when they could be procured.

Before the patients had arrived at Bathurst, they had generally recovered

from the regularly-marked symptoms of scorbutus; and my attention was principally called to the affection of the chest attempted to be described. The forms of it, however, were so various, as to cause me considerable embarrassment; and, moreover, the men were extremely irregular in their conduct, and gave themselves up to frequent intoxication, insomuch that their persisting disease appeared to arise more from their irregularities than to be the sequelæ of scurvy; therefore, I seldom did more than administer emetics and purgatives, of tartar emetic, calomel, and Epsom salts. Some I ordered to be blistered, or to have pustulation excited on the chest by tartar emetic ointment; but from the external applications little benefit was derived.

A few men who were suffering from other complaints before they got the scurvy, and some who contracted disease afterwards, chiefly from excess in drinking, remained long on hand; but, generally speaking, notwithstanding their irregularities, the scorbutic patients recovered favourably at Bathurst. The following is an outline of a few of their cases:—

CASE XII.—John Devine, 75th regiment, æt. 26, eleven years in the service, of healthy natural constitution, but given to drink, was taken ill at Fort Wellington, in August 1836, with sore and tender gums. He fell away in flesh, and felt weak, but was able to continue at his duty for five weeks after contracting these symptoms, when he was sent to regimental hospital at King William's Town. His left leg had become black; the knee, leg, and ankle swelled, and his mouth continued sore; and as he was not getting better, he was sent, in November, to Graham's Town. In his regimental hospital at King William's Town, he says that he got half diet, with wine and porter, and that when he was sent to Graham's Town his gums had grown over his teeth. The pain of his legs, and tenderness over his whole body, were excessive, and he had withal become so weak, that he was unable to rise, or to turn himself in bed. He gradually recovered there, and in the month of December was sent in a convalescent state to Bathurst, his only complaint being weakness.

CASE XIII.—Dennis Humes, 75th

regiment, *æt.* 30, twelve years in the service, states that he had been affected with a pulmonary affection, at Fort Cox, long before he got the "*black leg*," but was not medically treated for it. In July, at King William's Town, he was seized with pain in his ankles and legs, swelled and bleeding gums, shortness of breath, and pain in the back and chest. He was admitted into hospital there, kept his bed for fourteen days, and got some pills, brandy, and wine; and he was afterwards in quarters doing his duty for a month, when, in September, he was transferred as convalescent to Graham's Town, but was not taken into hospital, and in a short time was sent back to King William's Town, where he was soon obliged to go into hospital again, on account of pain in the chest. His mouth was not then sore, neither were his legs swollen nor black; but after being in hospital nine days, he was transferred to Bathurst in the beginning of December, his only complaint being pain of the chest, which appeared to me to be the effect of, or to be kept up by, intemperance. On the 23d February he was sent from Bathurst, on account of being an habitual drunkard.

CASE XIV.—Cornelius Ahem, 75th regiment, *æt.* 30, twelve years in the service. In 1834 had dysentery and eruptions on the skin. In October 1835, while at Fort Warden, in the New Province, he got a pulmonary attack; and in July 1836, he got the "*black leg*," with pains in his ankles and loins. He fell off in flesh, felt very weak, and his mouth became tender and sore. In September he was sent to King William's Town, was in hospital there only two days, and got half diet, with half a gill of brandy daily, and was then transferred to Fort Willshire, where he recovered from the black leg and soreness of the mouth; but as cough and pain of the chest continued, in the end of December he was sent to this place, where he has had no scorbutic symptoms; and he has been treated by venesection and blisters to the chest, together with antimonials and purgatives, for the pulmonary affection.

CASE XV.—William Patterson, 75th regiment, *æt.* 40, twenty years in the service. In June 1836, while stationed at Fort Waterloo, was seized with head-

ache, giddiness, and cough, lost his appetite, and could not sleep, but was still able to continue at duty for a fortnight, when his legs became swelled, hard, and black, and his mouth and gums tender and sore, upon which the pain of his head ceased. In July he was sent to King William's Town, to hospital, where he remained a month, got a pint of porter and two gills of wine daily, and had vinegar, salts, nitre, and other medicines, but did not get better, and was sent to Graham's Town in the latter end of August. He was not taken into hospital there, but remained in barracks, where he had wine daily; and in October he was well enough to be sent back to his regiment at King William's Town. On his journey thither he was exposed to wet and cold, and his gums again became sore; but there was no return of the discoloration of the legs. He was admitted into hospital, and remained in it a week, after which he was transferred to Fort Willshire, and in the end of December came to Bathurst, his symptoms being weakness, and pain in the back, shoulders, and chest, with a hard tumor on the sternum, and others of the same nature on the head, but which did not appear to be of a scorbutic character. He still remained in hospital.

CASE XVI.—John Sadler, 75th regiment, *æt.* 43, twenty-five years a soldier. In July, when at King William's Town, he got pain and swelling of the right foot, ankle, and whole of the limb, and was taken into hospital. The limb became black from the hip to the heel. His mouth had been sore from the commencement, and he had frequently felt sick and qualmish. He got half a bottle of porter and two gills of wine daily, with some lemons and vegetables, and often salts; and he had alum gargles for his mouth. He remained fifty days in hospital, but got weaker and weaker, until at last he was unable to leave his bed; and in this state he was removed in a waggon to Graham's Town. He was there taken into hospital, and got little medicine, but good diet, with plenty of vegetables; and after twenty-four days he was able to leave his bed. Soon after this his mouth got well, and the swelling and blackness of the limb subsided; but the contraction and stiffness of the knee-joint continued. In November he was

transferred to Bathurst, at which time he was not scorbutic, but still affected with this contraction, and also with pain and oppression of the chest, which he says he first felt at Fort Cox in 1835. He remains in hospital under treatment.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

CERTIFICATES FOR INSURANCE OFFICES.

WE are glad to see that the certificates which medical men sign for patients who want to insure their lives, have become the subject of warm and repeated discussion; for the common-sense conclusions to which such an investigation must inevitably lead, will be beneficial, in the first place to the profession, and secondarily to the public at large.

The first point mooted is, whether the medical practitioner who signs such a certificate, ought to be paid at all? In any profession but ours, such a question would be thought to savour of insanity. If a man were to expect a surveyor to draw up a detailed account of the dilapidations of his house gratis, or if he were to hope to get a written opinion on some legal subtlety from a barrister, for nothing, we suspect that it would go rather hard with him on a writ *de lunatico inquirendo*. The jury would infer, with some reason, that a man so grossly ignorant of the ordinary affairs of the world was incompetent to take care of his own property. With us, unluckily, matters are very different. There is a large heretical sect in society who seem to think that in the higher walks of our profession, at any rate, gratuitous services should be the rule, and payment the exception; that peers of the realm, and

great landholders, may pay; but that friends, and friends' friends, should be privileged to the fourth link of connexion: bits of paper must, of course, be signed gratis; to take a fee for such a thing as a certificate when offered, far more to demand it, would be "shabby." We begin, however, to have a glimpse of better days; the dictates of common sense are listened to, and practitioners in various quarters have declared that they must be paid for filling up these same documents, however much interested parties may disapprove of such proceeding.

We think it is very obvious, also, that these certificates deserve more than a common fee. A written opinion necessarily involves a greater responsibility than the ordinary revocable advice given to a patient—*littera scripta manet*; besides, it is really a much more difficult task to strike the balance of a man's constitution—to weigh his headaches in one scale and his equable pulse in the other, and from many minute circumstances to decide whether he is a good life, than to judge from present symptoms what medicine or diet is likely to relieve him. Hence we should think a fee of two guineas a very moderate recompense for such a service.

But a far more difficult question remains to be decided, namely, by whom ought the practitioner to be paid?

At first sight it might seem that the insurance office ought to pay; partly because the formal application to the medical man comes from the office, and partly because the insurance company gains by the bargain. The former of these reasons is rather a trifling one; for if in equity the patient ought to pay, it might easily be arranged that the application should come from him, or that he should repay the company for the fee given to his medical attendant.

That it is the company which gains by the transaction, if not a more substantial, is a more plausible argument;

for as the tables on which their policies are founded are formed from the duration of ordinary lives, and the company takes none but the most select lives at the ordinary premium, it requires but a glance to see that the balance of policies must be extremely advantageous to them; and accordingly we find that any great insurance office which has lasted for fifty or a hundred years, counts its gains by thousands and hundreds of thousands. Of late, indeed, we have had some insurance companies whose tables are founded on calculations taken from more picked lives, and who consequently give more favourable terms. Still, however, their tables do not come up to the actual average of life among the classes who insure, and the resulting profit is considerable. As the mass of policies, therefore, produce a profit, each insurer may be said to lose something; for it would be illusory to take, as some do, the case of a man who dies immediately after having insured his life, and contrasting the large gain which accrues to his family with the small gains derived by the company from a number of policies, to exclaim, see how much is gained by the insurer in one instance, and how little by the company in each of the others. This is as inconclusive as if we were to reason on a single case of the contrary kind, where the insurer continues to pay his annual contribution into the joint-stock treasury for fifty or sixty years, till he has paid double the amount of his policy, and till, perhaps, all whom he originally intended to benefit have disappeared from the stage of life.

When the problem is fairly stated, and accurately solved—that is, when the results of a large number of policies are balanced, the company always turns out to have been the gainer; and therefore each insurer may be considered a small loser. But this trifling loss is much more than counterbalanced by two great

advantages; namely, the freedom from anxiety, and the forced economy, which attend it. Supposing it to be certain that some one out of a thousand persons would be subject every year to a loss of 500*l.*, how great an advantage it would be if each person could be secured against the possible calamity by an insurance of twelve shillings per annum, even though this would be twenty per cent. more than his share of the loss. Would not the freedom from anxiety be worth the extra two shillings? Again, the forced economy, in our profession especially, is an immense gain, an absolute blessing. How few medical men, with an income varying from 800*l.* to 1200*l.*, would steadily lay by 150*l.* or 200*l.* yearly. So many temptations to increased expense come in their way—so many fond hopes would be cherished that a dash would take the town by storm, and that the shadow would produce the substance—that the attempted economy would rarely be continued; but a life-insurance once begun, cannot well be dropped; and the sum to be annually paid is soon looked upon in the same light as house-rent and taxes.

The bargain, therefore, being essentially an equal one, between the insurance company on the one hand and the mass of insurers on the other, it seems reasonable enough to conclude, that as the office pays its own medical adviser, the insurer should pay his.

It has been anticipated as a possible inconvenience, that, in a few disputed cases, the evidence of the patient's medical attendant might be weakened by the fact of his having been previously paid for it. The same kind of objection, however, that would then be made to the certificate, might be made even now; for if the opposing counsel is to suppose a practitioner so dishonest as to give a false certificate for a two-guinea fee, he might still more plausibly

allege that he had falsified the document from the hope of retaining an old patient—a sort of life annuity. We do not ourselves think any thing of this objection, nor imagine that paid certificates would lose their credibility. On the contrary, from the greater care with which they would unquestionably be drawn up, they would have the additional value which punctilious accuracy inevitably confers. Those who are afraid of a diminution of credibility in the evidence of the patient's medical adviser, if paid by him (like those who imagine that the bargain is a gainful one to the company alone), propose that he shall be paid by the company. To this the plain objection is, as before, that the contract being advantageous for both parties, the preliminary expenses should be divided between them. Mr. Farren, however, the resident director of one of the life-offices, has ferreted out another objection (a curious one enough). He says, "The business in which I have been actively engaged for fifteen years has brought me acquainted with many hundreds of medical professors who do not need my feeble testimony in favour of their acumen, liberality, and honourable feeling; but, sir, as there must be unworthy as well as worthy persons in all professions, it is sufficiently obvious that a very profitable source of business might be created for dishonourable practitioners, or rather for those who had no practice at all, from the concession sought by the Leeds combination. Men who never intended to complete insurances might make numerous proposals, with the certainty that the medical referees would be enriched, although the offices would as certainly be the losers of the fees they were silly enough to pay on faith of such references*."

To this, a writer, under the signature of W. A. W., in the *Times* of Novem-

ber 15th, replies, that this difficulty might be got over by paying the fee in those cases only where the insurance is effected. Let us observe in our turn, upon this, how readily medical men are thrust to the wall upon all occasions. If (to return to our old instances) a surveyor makes out a list of the dilapidations of a house, no one dreams that he is not to be paid because the vendor and purchaser cannot come to terms. Or suppose that the other day, when Sergeant Talfourd gave his written opinion as to the lawfulness of doctors talking publicly upon the unwholesomeness of arsenical candles, he had said "No!" instead of "Yes!" and thus put a gag on a hundred eager mouths, would the client have thought of withholding the fee, or rather of asking for it back again?

Mr. Farren makes another objection, which, we humbly submit, is even weaker than the last one. He supposes a fraudulent transaction, where rupture, fistula, hæmoptysis, or some other grave disease, has been concealed, and where the insured life of a man of thirty is not equal to that of a hale man of sixty. In such a case the directors would now bring evidence to show that the proposer's witness was a rogue, and had wilfully concealed an important fact; but Mr. Farren thinks that, under the new system, this could not be done, and that judge and jury would unite in saying to the directors, "this is your own witness, and you are bound to believe his statements." This we believe to be a grievous mistake; for it is quite obvious that the extraneous testimony which is now admitted to rebut that of the proposer's witness, would be equally good then, particularly if the company had consulted the witness at the request of the proposer.

We think it needless, however, to enter into a disquisition on this point, or to lose ourselves in the intricacies of the

* Letter in the *Times* of November 6, 1837.

law of evidence, as we have already given it as our opinion that the insurer ought to pay for his own witness; but then the witness ought to have his remuneration secured to him, and we would propose an arrangement by which almost every inconvenience might be avoided. It is, that the medical man, the insurer's witness, should in the first instance be paid by the office, and that this should be repaid by the fee being charged upon the policy. This would place the medical man in a very different position from that which he now occupies — he would know where to apply for his fee, and would have no difficulty in doing so; whereas at present he often does not, at the time, even see the party to whose general state he certifies; and if he did see him, would often, if not always, go without his fee rather than be compelled to ask for it.

As for the duty of medical men, it is clear enough; singly, or in combination, they should follow the example of the practitioners of Leeds, who passed a resolution some few months ago, stating that they would in future return the questions of insurance companies unanswered, unless accompanied by a suitable fee. Those, however, who think with us that the contract between the company and the insured must, in the long run, be advantageous for both parties, will not encumber their resolution with the words adopted at Leeds, "considering that the insurance company is the party benefited by the information thus obtained." Who gains most by the contract is a matter of indifference to the medical practitioner; he should act with the utmost impartiality, and send back without answer the unballasted questions that are thrust upon him, from whatever quarter they may arrive:

Tros Rutuluse fuat, nullo discrimine habeo!

ANIMAL MAGNETISM.

At page 291 will be found a communication from M. le Baron du Potet, for the insertion of which he has trusted to our "justice" and "impartiality." *Audi alteram partem* is an appeal which, couched in temperate and courteous language, as in the present instance, and confined within reasonable limits, it would be unhand-some to disregard. We have therefore complied with his request; nor, as to the rest, do we think that an historical sketch of Mesmerism will be without its interest to our readers.

ST. GEORGE'S HOSPITAL.

Punctured Wound, involving the Diaphragm, Spleen, Stomach, and Liver.

JAMES RANDALL, æt. 40, valet, was admitted into St. George's Hospital, November 3, 1837, under Sir Benjamin Brodie, with punctured wound in the side. He was admitted at 2 p.m., having received a stab with a table-knife but a short time before. There was found a wound about an inch and a half long, on the left side, just below the true ribs. The policeman stated that the blade of the knife was stained with blood for four inches and a half of its extent. It was noted by the house surgeon, Mr. Berkeley, that his extremities were cold, pulse feeble and slow, countenance pale and anxious, with but little bleeding from the wound. Bottles of hot water were applied to his feet, and lint, plaster, and wet compress, to the wound.

Three hours after his breathing became difficult; his pulse rose in frequency, but was very small and compressible.

Ten hours after he was bled to 3x., and the following was prescribed:—

Hydrargyri Chloridi, gr. x. statim in formâ pulveris, c. haustu sequente.

Misturæ Camphoræ, ʒiiss.; Liqueoris Opii Sedativi, ℥xxv. M.

12 hours.—The pulse, which had sunk, is now nearly the same as before the bleeding; he breathes more easily.

16½ hours.—Complains of pain over the surface of the abdomen.

Fotus abdomini.

20 hours.—Pulse continues very frequent; pain more severe.

V.S. ad ʒviij. Hydrargyri Chloridi, gr. iij. 6tis horis.

23 hours.—Pain in abdomen undimi-

nished; he shrinks under pressure. Hiccup; pulse 140, very small; bowels not open.

Hirudines xx. abdomini; postea fotus.

24 hours.—Soon after the leeches were put on he became so weak that they were immediately removed, and the bleeding stopped. The coffee and tea which he has been drinking has, within the last half hour, begun to run out through the external wound; pain over the abdomen considerable; extremities cold; skin perspiring; extreme thirst. An injection of warm water and oil was administered, and a quarter of a grain of opium was added to each pill.

26 hours.—Complains of a desire to make water; the catheter was passed, and one ounce drawn off. Pulse very rapid and weak; very anxious expression of countenance.

28 hours.—His pulse has been gradually getting weaker, and his extremities more cold. Very soon after this report he expired.

I am indebted for the above detail of his symptoms to Mr. Berkeley, the house-surgeon, who noted down his symptoms every two hours.

Post-mortem examination.—The tenth rib, over which the wound was situated, was fractured obliquely from behind forwards. The instrument had penetrated the space between the tenth and eleventh ribs, passed through the pleura and diaphragm, but produced no injury of the lung, further than slight ecchymosis of the contiguous portion; it then glided through the upper and fore part of the spleen, and passing posterior to the gastro-splenic omentum, without injuring the colon, penetrated the coats of the stomach immediately posterior to where the anterior and posterior layers of peritoneum pass off to inclose the spleen: then coming out at the anterior surface of the stomach, at its left side it had plunged into the substance of the left lobe of the liver, at the middle of its inferior concave surface, and having passed through, came out at its superior surface, midway between its anterior and posterior margins, about one inch from the suspensory ligament, and was then arrested by the posterior surface of the sternum, where there is a fissure left, as made by a knife or some sharp instrument, close to the articulation with the fourth rib. There was a considerable quantity of blood collected in the cavity of the peritoneum. About the middle of the superior convex surface of the liver was a circular spot of ecchymosis, about the size of a shilling. The spleen was very much enlarged, and turgid with dark blood. The

stomach was very flaccid, and contained much bile and glutinous fluid, which was collected at its pyloric extremity. The duodenum was filled with fluid matter, and its coats congested with venous blood. The coats of the jejunum were also similarly congested, but to a less extent; they were thickened more than naturally. The ileum was empty and natural, except at its inferior extremity, where there was much ecchymosis under the serous coat.

The right testis was smaller than natural. There were two flat circular cicatrices, or rather scars of former ulcers, on the glans penis, at the inferior part, one on either side of the frænum. Some sebaceous secretion was collected behind the corona glandis.

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Mr. ANDREWS, *Surgeon*.

Mr. ADAMS, *Assistant-Surgeon*.

Oct.	Sex.	Age.	Case.
31.	M.	31	Scald.
	M.	26	Compound fracture of the lower jaw.

Observations on the Result of Amputations in this and other Countries. By BENJAMIN PHILLIPS, F.R.S.

THE object of the author, in the paper now presented to the Society, is, in the first place, to prove that the opinion commonly entertained with respect to the mortality succeeding to amputation is incorrect; secondly, to exhibit the results of inquiries undertaken in France, Germany, America, and Great Britain, as to the mortality consequent upon this operation, and to compare these results with each other, for the purpose of ascertaining to what extent is justified the belief in the greater success of amputation in our own than in other countries; and thirdly, to adduce evidence in proof that the treatment commonly employed in certain cases of old-standing disease, is less favourable in its results, and less in consonance with pathological principles, than that proposed by himself, in the course of the present inquiry. The author lays much stress on the importance of possessing more exact records of the results of operations in large hospitals, as the only sure data upon which to found a judgment of their comparative safety; the memory of individuals being, as he has often had the opportunity of proving, quite insufficient to furnish even an approximation to the truth. The author admits that many hospitals may be so circumstanced, either permanently, or at particular periods, as that the results of amputations in them should seem to be peculiarly unfavourable; but he has endeavoured to obviate this difficulty by making such a selection as would produce something like a compensation in this respect. The amputations included in this inquiry, are those of the arm, and the forearm, the thigh, and the leg; all have been performed within the last four years in civil hospitals, or in the private practice of hospital surgeons. The gross number of such cases is 610. Of these, 490 are reported "cured," and 150 died, either in consequence of the operation, or from the progress of the disease for the relief of which it had been performed. The author proceeds to analyze the gross number, and exhibit the proportion furnished by the different countries comprised in the inquiry, in a table, from which it appears that the proportion of deaths after amputation, in Great Britain and France, is a fraction below, while in Germany and America it is a fraction above, the average. It would be impossible to detail, within the limits of a brief abstract, all the observations upon which the author founds the opinion that the amount of mortality is greatly increased by the almost entire abandonment of the system of consecutive union of stumps, resulting

from the amputation of long-standing chronic diseases, attended with profuse suppuration; an opinion which leads the author to recommend a modification, in such cases, of the present mode. Although the author is not an advocate for the substitution of consecutive for immediate union, in any class of cases, he is strongly impressed with the opinion that many of the evils resulting from immediate re-union, in an extensive class of cases, might be obviated by establishing, in the vicinity of the part where amputation is to be practised, an artificial suppurating surface, by means of a seton or issue, and maintaining such secretion for a time after the healing of the stump. The author professes to have no direct evidence of the efficacy of the proposed modification; but he thinks himself warranted, by the premises, in maintaining the probability that it would render unnecessary the plan of having recourse to secondary union, whose advantages in any cases are almost counterbalanced by great inconvenience.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, Nov. 16, 1837.

Job Harrison, Chester.—Jenner Plomley, Sussex.—E. H. S. Banks, Folkestone.—E. C. Seaton, Kent.—Rice H. Anwyl, Bala, Merionethshire.—G. J. Parker, Bristol.—G. E. Williams, Brighton.

WEEKLY ACCOUNT OF BURIALS,

From BILLS OF MORTALITY, Nov. 7, 1837.

Abscess	1	Heart, diseased	2
Age and Debility	30	Hooping Cough	6
Apoplexy	8	Inflammation	18
Asthma	12	Bowels & Stomach	5
Cancer	1	Brain	3
Childbirth	5	Lungs and Pleura	3
Consumption	50	Insanity	5

LECTURES

ON

FORENSIC MEDICINE;

Delivered at the Aldersgate School of Medicine.

By SOUTHWOOD SMITH, M.D.

Physician to the London Fever Hospital.

LECTURE II.

ON EVIDENCE.

Acquaintance with the nature of Evidence necessary to the Medical Witness—Insufficiency of Common Sense—Desirableness of Systematic Knowledge—Sources from which such Knowledge may be derived—Evidence—Testimony—Complex Evidence—Facts the subject-matter of Evidence—Principal and Evidentiary—Physical and Psychological—Positive and Negative Facts—Cause of Belief in Evidence—Analysis—Experience—Mental Law to which belief in Evidence is referable—Experience the ground of Belief in Evidence—Cause of Belief in Testimony—Personal and Real Evidence—Personal Evidence, voluntary or involuntary—Testimonial Evidence, original or unoriginal—Real Evidence.

Acquaintance with the nature and evidence necessary to the medical witness.—Before entering on the individual topics which form the subject matter of the present course, there is one thing to be considered, which is to forensic medicine what anatomy is to surgery. In a surgical operation not a single movement of the hand can be made with the prospect of advantage, nor even with safety to the patient, unless it be guided by an intimate acquaintance with structure. As medical witnesses, you can neither collect the facts which are required to guide the jury and the Judge, nor, when you have collected them, state them with the requisite clearness, exactness, and force, unless you understand the nature of evidence.

Yet this important subject has, in

general, been so much neglected by the members of our profession, that there are many amongst us who have no correct conception even of the very meaning of the term; and there are few who have ever taken a comprehensive and scientific view of it.

Insufficiency of common sense.—Some may even regard an account of evidence in general, as unnecessary in relation to forensic medicine, although forensic medicine is merely the application of a particular species of evidence to a special purpose. The facts, it may be said, which form the subject matter of the evidence which the medical witness is called upon to give in a court of justice, must be familiar to every well-educated medical man. It can require but little art to collect them; it must be easy to state them; and on this, as well as on so many other subjects, common sense is a reader and safer guide than science.

The answer to this sort of cloak for indolence and ignorance has been given in a masterly manner by a distinguished logician of our own day, in the following words: "There are many," says Archbishop Whately, in his *Treatise on Logic*, "who allow the use of systematic principles in other things, who are accustomed to cry up common sense as the sufficient and only safe guide in reasoning. Now, by common sense is meant, I apprehend, (when the term is used with any distinct meaning) an exercise of the judgment unaided by any art or system of rules; such as we must necessarily employ in numberless cases of daily occurrence; in which, having no established principles to guide us,—no line of procedure, as it were, distinctly chalked out,—we must needs act on the best extemporaneous conjectures we can form. He who is eminently skilful in doing this, is said to possess a superior degree of common sense. But that common sense is only our *second-best* guide—that the rules of art, if judiciously framed,

are always desirable when they can be had—is an assertion, for the truth of which I may appeal to the testimony of mankind in general, which is so much the more valuable, inasmuch as it may be accounted the testimony of adversaries. For the generality have a strong predilection in favour of common sense, except in those points in which they respectively possess the knowledge of a system of rules; but in these points they deride any one who trusts to unaided common sense. A sailor, for example, will perhaps despise the pretensions of medical men, and prefer treating a disease by common sense; but he would ridicule the proposal of navigating a ship by common sense, without regard to the maxims of nautical art. A physician, again, will perhaps condemn systems of political economy, of logic, or metaphysics, and insist on the superior wisdom of trusting to common sense in such matters; but he would never approve of trusting to common sense in the treatment of diseases. Neither, again, would the architect recommend a reliance on common sense alone in building; nor the musician in music; to the neglect of those systems of rules, which, in their respective arts, have been deduced from scientific reasoning, aided by experience. And the induction might be extended to every department of practice. Since, therefore, each gives the preference to unassisted common sense only in those cases where he himself has nothing else to trust to, and invariably resorts to the rules of art, wherever he possesses the knowledge of them; it is plain that mankind universally bear their testimony, though unconsciously and often unwillingly, to the preferableness of systematic knowledge to conjectural judgments."

Desirableness of systematic knowledge.—I hope I need say nothing more to engage your attention to the attempt I am about to make to put you in possession of systematic knowledge, on a subject which may be regarded as the basis of forensic medicine. If the exposition which I propose to give of the general nature of evidence should convey to you a clear and accurate conception of this subject, the rules which should guide you in the collection and deposition of evidence in relation to your own particular department—that is, the application of the general doctrine of evidence to the particular subject of forensic medicine, will be easy, striking, and most instructive.

Sources from which such knowledge may be derived.—It would be altogether out of place, on the present occasion, to enter much into detail. The most that your time will allow me to attempt, is to indicate the main points which deserve your attention. You will

find minute and ample information in the great work of the English jurist, the illustrious Bentham, entitled "the Rationale of Judicial Evidence," in which he has entered into a profound and detailed investigation of the subject, and has wrought out every point with a degree of completeness which leaves hardly any thing more to be done or desired. You will also find a brief but clear analysis of evidence in Mr. James Mill's masterly "Analysis of the Phenomena of the Human Mind." In relation to this subject, you should also read with particular care that portion of Professor Brown's "Lectures on Moral Philosophy," which treats of cause and effect; and Dr. Whateley's (the Archbishop of Dublin) "Treatise on Logic." The attainment of the mere knowledge, inestimable as it is, contained and unfolded in these works, is the least part of the advantage they are capable of affording: the great benefit to be derived from their diligent study, is the habit of correct reasoning, to which such study tends to train the mind, and which, once formed, will render the acquisition of any branch of knowledge to which the mind can apply itself, easy and sure.

Evidence.—A sailor, shipwrecked on an unknown coast, sees the print of a man's foot on the sand. The perception of this foot-print produces in his mind the belief that a man has been present in that place. Here, then, are two events; the first the antecedent, the second the sequent; the latter produced by the former. The first, the antecedent, the footmark on the sand, induces the belief of the second—the sequent, the existence of a man. Now, the first event, the foot-print on the sand, is called the evidence; the second event, the persuasion produced of the existence of a man, is denominated the belief induced by the evidence.

Testimony.—The sailor who has seen the foot-print reports it to his companions who have not quitted the wreck. Instantly they have the same belief. In this case the report of the sailor to his companions is called testimony; the effect produced upon their minds, namely, the persuasion of the existence of the event testified to, is denominated belief in testimony.

The first event to the sailor is an object of sense; this is to him evidence of the second event. The first event to his companions is the affirmation of their comrade; this is to them evidence of a second event, the existence of the print; and this is evidence of a third event, the existence of a man. Here, then, is what is termed evidence of evidence; the testimony, evidence of the print; the print, evidence of the man.

Complex evidence.—If the evidence con-

sist of more than one event, it is said to be complex. Thus, after discovering the print on the sand, the sailors found a stick, fashioned into a club; on searching further they discovered a spear, and at some distance they saw the embers of a recent fire. These circumstances are all so many additional events, tending to produce the same belief, namely, the presence of men in this place. Now, the whole of the events which go in this manner to form a case of belief, constitute the evidence of that case.

Facts the subject-matter of evidence.—We now, then, can form a clear conception of the nature of evidence. The term evidence expresses a fact, the tendency of which, when presented to the mind, is to produce a belief in the existence of some other fact. These two facts bear to each other, as I have stated, the relation of antecedent and sequent.

Principal and evidentiary fact.—The first fact, the antecedent, is always a fact already known; the second, the sequent, is never a fact already known, but a fact to be sought. This latter, the fact sought, is termed the principal fact; the former, the fact already known, is called the evidentiary fact, because it affords evidence of the existence of the fact sought.

Poison is suspected to have been administered to a deceased person by a particular individual; that is the unknown fact—the principal fact—the fact sought. The facts known, the evidentiary facts, are, that the suspected person is discovered to have had poison in his possession; that he was observed to give the deceased the last thing she drank; that by an eye unseen he was detected in slipping something secretly into the cup; that soon after taking the contents of this cup the symptoms of poisoning came on, and so on. Suppose the existence of these facts to be without doubt, it is clear that the tendency of each of them is to produce in the mind a conviction of this other fact, that the individual in question really did administer the poison. The facts bearing on this point, and having this tendency, are all evidentiary facts; and the whole of them taken together constitute the evidence of the case.

Facts having such and such a tendency are also termed circumstances. Any fact may be a circumstance with reference to any other fact; *CIRCUMSTANTIA*, standing about or around—objects by which a given object is encompassed, which may be considered as standing around it.

Physical and psychological facts.—Facts, whether principal or evidentiary, are of two classes—physical and psychological. A physical fact is one which belongs to some physical body; a psycho-

logical fact is one which belongs to some living being. Physical facts include the whole range of phenomena comprehended in the inorganic world, and form the subject-matter of natural philosophy; psychological facts include the whole range of phenomena comprehended in the world of mind, and form the subject-matter of mental philosophy.

States of things are also termed facts, and so are events. By an event is meant some motion which comes about in the course of nature. The fall of a tree is an event; the existence of the tree is a state of things: both are alike facts.

In like manner an action, a name given to an event which has its source in the human will, is termed a fact.

Positive and negative facts.—Facts are either positive or negative. A certain thing exists, and is designated by a certain name. This constitutes a positive or an affirmative fact. The declaration of the non-existence of that thing constitutes a negative fact; but it must be at once obvious to you, that the only really existing facts are positive facts; for a negative fact is nothing more than the non-existence of a positive one.

Cause of belief in evidence.—When an evidentiary fact is presented to the mind, we believe in the existence of the fact evidenced to, the principal fact. This belief is a part of our nature; it is a part of the constitution of the human mind. It does not depend upon our will. We believe, and we cannot do otherwise. When an evidentiary fact possesses a certain degree of strength, we can no more help believing in the existence of the fact of which it is the indication, than we can help the sensation of light when we direct our eyes towards a luminous body.

What is the cause of this belief in evidence? If as mental analysts you trace this remarkable psychological phenomenon back to its source, you will find that it is referable to the mental law which is termed the association of ideas.

Analysis.—During the whole course of our lives we are witnesses of incessant trains of events. The events of which these trains are composed succeed each other in a certain order. Some are antecedents, some are sequents. Between some antecedents and some sequents, we observe that the order is constant, that the connexion is invariable. We never see the one take place without the other. We never see that the one is sometimes the antecedent and sometimes the sequent; but we observe that the antecedent is invariably the antecedent, and the sequent invariably the sequent. Now in all the cases in which we observe this constant, this invariable conjunction between two events, an association is

formed in our mind between them, in the order in which they take place. The association of the two events in the mind is as inseparable as the combination in which they occur in nature. A stone thrown into the air falls to the ground. Between the antecedent, the stone thrown into the air, and the sequent, the falling of the stone to the ground, the connexion is fixed and invariable. The idea of the one calls up the idea of the other. Do what we may, we cannot think of the one without thinking of the other. The two ideas are forced upon us at the same time, and in the same order; and by no effort which we are capable of making can they be disjoined.

On the other hand, in regard to a great number of events, we observe that there is not between them this constant conjunction; that they do not bear to each other the relation of invariable antecedents and sequents; that sometimes one happens without the other; and that, when they do happen in conjunction, they occur sometimes in one order, and sometimes in another. The crow flies sometimes north, sometimes east, and sometimes west. For ought we have observed, it flies as often in one direction as in another. The consequence is, that no association is formed in our minds between the flight of the crow and its flight in any particular direction. But no instance has ever been witnessed by us, in which a stone thrown into the air did not fall to the ground; consequently between the idea of a stone thrown into the air, and the idea of its falling to the ground, there is formed in our minds an indissoluble association.

One remarkable circumstance connected with these two different classes of events, is, that the events which are found to have no necessary connexion with each other, pass readily out of the memory, and are soon forgotten; while the events between which a constant connexion is observed to be established, make a deep and lasting impression upon the mind, and cannot be forgotten. From the first moment of our consciousness, we have been incessantly employed in observing these constant conjunctions of events. We have had the greatest possible interest in looking out for, and ascertaining them. All that we know of external nature—all that we know of ourselves—all that we know of the influence of physical agents upon our own living organization—all that we know of good and evil to ourselves and others, is most intimately connected with these observed, these ascertained antecedents and sequents. Without a knowledge of many of these constant conjunctions of events, we could not maintain our existence for a single moment; and

in general, when we increase our stock of knowledge, we do nothing more than merely add to the number of events which we previously knew to have this relation of constant conjunction,—other events which we now for the first time ascertain to have that same relation.

Experience.—And it is this which constitutes our experience. That stock of accumulated knowledge to which we give the name of experience, consists of a number of events the existence of which we have ascertained, and between which we have discovered, or suppose we have discovered, either that there is a constant conjunction or that there is not. In proportion to the number of events the existence of which we have ascertained, is the extent or range of our experience; in the degree in which our notion of their constant conjunction or non-conjunction is just, is the soundness of our experience.

Mental law to which belief in evidence is referable.—There is no analysis of a compound substance, effected by the modern chemist, more complete and satisfactory than that accomplished by the mental analyst, when, by the resolution of compound ideas into the elements of which they are composed, he succeeds in progressively tracing back some of our most complex states of consciousness to the simple mental law of association; which is to mind, what gravitation is to matter. From what I have already said, you will be able clearly to see that what we call belief in evidence is referable to this mental law; and you will be able, each for himself, to trace it back to this law.

You have observed the invariable conjunction between two events—the invariable relation of antecedents and sequents. The existence of one of these events, the sequent, is made known to you: instantly you are convinced of the existence of the other, the antecedent. Why? Because, by reason of the indissoluble connexion between the two events already established in your minds, through the operation of the law of association, you believe (and you cannot but believe) in the existence of the antecedent, the moment you are satisfied of the existence of the sequent.

Such, then, is the cause of the belief in evidence. It is the necessary result of that constitution of the human mind by which such an association is formed between two events, observed to occur in invariable conjunction, that the one cannot be presented to the mind without its calling up the presence of the other.

“This is no more Daniel Clarke’s bone than it is my bone!” exclaimed the murderer Houseman, when examined at an inquest on a skeleton that had been accidentally found in a field.

This man, whose habits were known to be profligate, and whose disposition was deemed ferocious, had long been suspected of having been concerned in the murder of a person of the name of Clarke. Fourteen years had elapsed since the event. The skeleton now found was supposed to be that of Clarke.

Housman, on being examined touching the matter, betrayed some confusion—indicated something of that involuntary emotion which results from what is commonly termed being conscience-stricken.

As if to divert attention from this, he suddenly assumed an air of levity, and, taking up one of the bones of the skeleton that lay beside him, exclaimed, "This is no more Clarke's bone than it is my bone."—"Then," instantly inquired the examiner, "where are Clarke's bones?" This unexpected question threw the conscience-stricken criminal off his guard. He could not conceal that he knew; he turned King's evidence; denounced Aram as the murderer; admitted that he had been an accomplice, and described exactly where the true skeleton would be found.

"In St. Robert's Cave (he said) it will be found, just by the entrance, and with the head towards the right."

There was found, exactly as described, a skeleton. On examining the skull, there was discovered a fracture on its left side, apparently produced by the stroke of some blunt instrument. The piece was beaten inwards, and could be replaced only from within.

"It is not a recent fracture (said the medical witness examined on the occasion). It could not have been produced by the instrument with which it was dug up. It appears to have been of many years' standing."

This is the story of the celebrated Eugene Aram.

It is obvious that this murder was discovered by a remote evidentiary fact, suggesting the principal fact. "This is no more Clarke's bone than it is my bone!" exclaimed the suspected murderer.

What was the train of thought that instantly passed through the mind of the examiner, on hearing this statement?

This is not Clarke's bone; you know that it is not; but you cannot know it is not, without knowing where Clarke's bones are.

If you know where these bones are, you probably know how they came where they are.

It is not likely that you can know how they came where they are, without knowing something about the circumstances of the death that preceded their being placed there.

What you know about such death, you

probably know from having been concerned in producing it.

Such was the train of thought. The evidentiary fact, the exclamation, suggested the principal fact—the perpetration of the murder. The knowing what the fact was not, suggested that there must be a knowledge of what the fact was. The connexion between the two was close and inseparable, and all that chain of reasoning which it has taken so much time to put into propositions, passed through the mind in an instant; for thought is quick.

That the suggestion and the reasoning were correct—that there was a real connexion between the events in question, is placed beyond all doubt, by the subsequent confession of the murderer by the murderer.

Experience the cause of belief in evidence.—From what has been stated, you can understand clearly what is meant when it is said that the ground of belief in evidence is experience. The fact observed by you, that such and such conjunctions of events are invariable, you are said to know from experience, because of the certainty of such facts your senses have given you uniform assurance; for all that you know from your own experience is resolvable ultimately into what you have been taught by your own sensations.

Cause of belief in testimony.—The cause of belief in testimony is perfectly analogous. That there exists in the human mind a propensity to believe in testimony, is matter of universal experience; and the like universal experience establishes the justness of that belief. Continue your belief in testimony as you have been accustomed to believe in it; the business of your life will go on according to its ordinary tenor: withhold your belief from testimony with the same regularity as that with which you have been used to bestow it, and if you should find it possible to preserve your existence at all, you certainly will not find it possible to preserve it without intense and unceasing suffering. On the knowledge you have of the states of men and things, depends the prosperity with which the business of your life is carried on; but of that knowledge, the portion which you can obtain from your own experience is but as a drop of water to the ocean; the rest of it of which you have need, must come to you, if it come to you at all, from testimony.

You believe, then, in testimony, and you cannot do otherwise if you would. Why? After what has been said of the cause of belief in evidence, you can be at no loss to assign the cause of belief in testimony.

A person bears testimony in relation to a certain event; the words of the testifier excite in your mind certain ideas in regard to the thing testified. Words call up ideas

by association. You know, from your own experience, the manner in which words are applied to events. From the first moment you have been capable of using words, or of understanding their import, you have employed them yourself, and you have observed them employed by others, in exact conformity with events. You have occasionally observed cases in which words are not employed in exact conformity with events, but these cases are few, in comparison with those in which they are so employed. The greatest liar that ever lived, speaks truth a thousand times for once that he utters a falsehood. In your ordinary intercourse with your fellow men, propositions affirming the existence of this or that fact are incessantly made, in a vast variety of forms. For the most part, as occasions arise in which you have an opportunity of verifying by your own perceptions whether the assertions made concerning these facts are conformable to the facts, you find that they are conformable. What is the consequence? That the connexion between the use of words, between affirmations and the idea of conformable existences, comes to be established as one of the strongest associations of the human mind.

The general conformity of testimony to the real state of things, of the facts reported upon to the reports made concerning them, is thus a matter of universal experience. Thus the ground of belief in testimony is experience, just as experience is the ground of belief in evidence; and an inseparable association being formed between the idea of the general conformity of the words of the testifier with the real state of the things testified, it is plain that the cause of belief in testimony is association, just as the same great mental law is the cause of belief in evidence.

"It is unaccountable that Asa should choose to be out of the way at such a time as this," said his mother, the wife of Ishmael Bush.

Esther and Ishmael Bush were the heads of a family of settlers in America, on those broad plains which stretch for immense distances to the basis of the Rocky Mountains. The wild position and habits of this party, and their perilous and spirit-stirring adventures, have been graphically depicted, by a masterly hand, in a narrative familiar to you all. Whether the narrative be fictitious or historical, it will serve the present purpose of illustration equally well.

Among the varied incidents described in this story, there is one in which an irresistible conviction that a certain individual had perpetrated a frightful crime, is produced by the testimony of a single witness, — a few words spoken by that witness pro-

ducing this conviction, even against evidence of no slight degree of force tending to produce a directly contrary persuasion.

In reply to the observation of his mother, that it was unaccountable that Asa should be absent at this particular time, Abiram, the brother of Esther, the uncle of the young man who was missing, the murderer of the youth, said, "it will be well if the boy has escaped the Tetons. I should be sorry to have Asa, who is one of the stoutest of our party both in heart and hand, fall into the power of the red devils."

The lad does not return; the family is thrown into a state of great alarm at his continued absence; and having set out in search of him, they at length discover the dead body in a thicket.

The two brothers who discovered the body, agree in their account as to the position in which they found it; seated nearly upright, the back supported by a mass of matted brush, and one hand still grasping a broken twig of the alders. Owing to the former circumstance the body had escaped the rapacity of the carrion birds long observed to have been hovering about the thicket; and the latter proved that life had not yet entirely abandoned the victim when he entered the brake. The opinion became general that the youth had received his death-wound in the open prairie, and had dragged his enfeebled body into the corner of the thicket for the purpose of concealment. A trail through the bushes confirmed this opinion. On a close examination of the spot it further appeared that a struggle had taken place on the margin of the thicket, as was apparent by the trodden branches, the deep impressions on the moist ground, and the lavish flow of blood.

"He has been shot in the open ground, and come here for a cover," said Abiram; "these marks clearly prove it. The boy has been set upon by the savages in a body, and has fought like a hero as he was, until they have mastered his strength and then drew him to the bushes."

On a careful examination of the corpse, with a view to obtain a more accurate knowledge of the injury sustained, it is found that a rifle bullet has passed through the body, entering beneath one of the shoulders, and making its exit by the breast. The very bullet is discovered. It is supposed to have come from the pouch of an old man, a wild hunter, a trapper.

"There is no mistake," said Ishmael. "Like many of the hunters he has a mark in his mould in order to know the work his rifle performs; and here you see it plainly—six little holes laid crossways."

"I'll swear to it!" cried Abiram, triumphantly. "He shewed me his private mark himself, and boasted of the number

of deer he had laid upon the prairies with these very bullets. Now, Ishmael, will you believe me when I tell you that old knave is a spy of the red skins?"

The traces of the different struggles which were to be seen between the spot where the first blood was spilt, and the thicket to which the murdered youth appeared to have retired as a place of refuge, were now interpreted into so many proofs of the weakness of the murderer, who would have sooner dispatched his victim had not even the dying strength of the youth rendered him formidable to the infirmities of one so old; while the danger of drawing some of the other hunters to the spot by repeated firing, was deemed a sufficient reason for not again resorting to the rifle after it had disabled the victim.

The trapper falls into the hands of the borderers, and is charged with the perpetration of the crime. The evidence adduced against him is the bullet found about the person of the murdered youth. "With this morsel of lead did he lay low as fine a boy as ever gave joy to a parent's eyes."

The defence of the accused was made in the following words:—"As we were all outlying about your camp, seeing that I was more skilled in scouting than the others, while they lay beneath in the cover I was sent upon the plain. As I lay in a low bed of grass I saw two hunters come nigh each other. Their meeting was not cordial, yet I thought they would have parted in peace, until I saw one put his rifle to the other's back and do a treacherous murder. The manly youth stood the shock for more than a minute before he fell. Then he was brought to his knees, and a desperate fight he made to the brake, like a wounded bear seeking a cover."

"Who was the perpetrator of this deed?"

"Yonder stands the man, and a disgrace it is to our race that he is of the blood and family of the dead."

"He lies! he lies!" shrieked Abiram. "I did no murder, I gave but blow for blow."

Ah! That exclamation, the admission implied in it, was a fatal confirmation of the testimony of the eye-witness. The conviction of the truth sunk into the heart of the most reluctant to believe it.

The voice of Ishmael was deep and even awful, as he answered—

"It is enough. Unbind the old man, and let him go. Boys, put the brother of your mother in his place."

Evidence personal or real.—Evidence is either personal, that is, afforded by a human being, a being belonging to the class of persons; or real, that is, afforded by a being not belonging to the class of persons, but to the class of things.

Personal evidence is either voluntary or involuntary.

Voluntary personal evidence is all such evidence as is afforded by means of language or discourse. This is the description of evidence commonly termed testimony.

Involuntary personal evidence is all such evidence as results from emotion exhibited not in consequence of any act of the will directed to that end, but frequently in spite of the will; in direct opposition to every exertion which the will can make. To this kind belong all the involuntary modifications of which the deportment, and all the involuntary changes of which the countenance is susceptible.

The subject of all personal and voluntary, and consequently of all testimonial evidence, is always either the very fact, the existence or non-existence of which is the principal matter of fact in question; or some fact which, though distinct from it, is considered as being evidentiary of it. Hence result two species of evidence, direct and circumstantial, to the distinction between which I shall direct your attention hereafter.

Testimonial evidence is either original or unoriginal: original, where the deposing witness states, that the matter of fact in question, at the time and place in question, fell under his own observation; unoriginal, when the witness speaks of some other person, and not himself, as the person to whose senses the matter of fact presented itself.

Things, in contradistinction to persons, may be the source of evidence; and all objects belonging to this class come under the denomination of real evidence. So extensive a source of evidence is this, that there is scarcely an object in nature which is not capable of becoming the subject of inquiry in a court of judicature. A person is killed or hurt! What are the objects capable of affording real evidence in relation to the event; the blood upon the ground; the instrument by which the injury was inflicted; the pistols, the sword, the club, the knife. Poison has been administered. A portion of some one of the different classes of poison is discovered in the house, in the chamber of the murdered person; in the possession of the suspected person. On examination of the body of the deceased, a portion of this very same poison is detected in the stomach or intestines. A house has been broken open, and a person murdered. There are found the pick-lock key, the crow, the chisel, the ladder; and even the very floor on which the person killed was standing, the chair on which he was sitting, the bed on which he was lying, bear witness to the kind of violence perpetrated.

PART III.

To the Editor of the Medical Gazette.

SIR,

HAVING in my former papers treated of the physiological principles on which the nature of the diseases we are considering depends, the immediate causes of those diseases, namely, the state of body which immediately produces their characteristic symptoms, and the manner in which this cause operates in producing their various phenomena; I am now to point out their remote causes, the manner in which they operate, and the general principles of the treatment which counteracts their effects, and which, as might be expected, has been found by many degrees more successful, than that which is founded on a mistaken view of the nature of those diseases; thus affording the most important and gratifying proof of the soundness of the view which has been taken of them.

It appears, from what was said in the last of the foregoing papers, that a state of continued general debility or nervous irritation, which indicates the existence of a cause which has to a certain degree debilitated the organs of the leading power of the vital system, may be of various origin. It may arise, we have seen, from original disease of its organs; it may be a sympathetic affection, arising from the state of the central organs of the sensitive system; or it may be the effect of disease in some other vital organ, directly influencing the state of the central organs of the vital system.

The first of these causes is of rare occurrence, the second less so; but it is to the last cause that, in at least nineteen cases of twenty, the disease must be ascribed.

Thus the most common cases are those,

the general character of which is given in the latter part of my last communication, consisting of the affection of some vital organ influencing the central organs of the vital system, and a debilitated state of these organs causing a third affection, that of some other vital organ, which always proves both the most prominent and formidable disease, because, as appears from what has been said, the affection of the organ in which the disease originates must have two conditions: it must belong to an organ little disposed to change of structure, and the affections of which in general are not immediately productive of alarming consequences. Without the former condition it could not be of so chronic a nature as to induce the debility of the central organs; and without the latter it could not be disregarded or lightly treated by the medical attendant; or, as not unusually happens, so disregarded by the patient, that medical advice is either not obtained or not regularly attended to; for although the symptoms appear little formidable, in order to produce the effect we are considering, they must always be obstinate or of frequent recurrence; for this effect seldom takes place except from repeated and long-continued causes of irritation.

I am now to inquire in what part of the vital system, that is, in what organs, such an affection is most apt to arise.

We should, *a priori*, expect to find it most frequently occurring in those organs which are most extensive, and consequently most capable of a powerful impression on the central organs of the brain and spinal marrow, and most exposed to causes of irritation; and yet not the most immediately essential to life, and therefore their functions such that they may be disturbed to a considerable degree, and for a considerable length of time, without immediately endangering it.

The organs to which these observations most eminently apply are the alimentary canal; but it is very unusual for irritations of this canal alone to produce the serious effects which form the subject of these papers, because, when its affections are unaccompanied by other disease, they are seldom of sufficient constancy or recurrence to induce debility of the central organs of the vital system. But this, however rarely, may happen. I shall state, in a cursory way, the circumstances of such a case,

because it is very uncommon, and particularly illustrates much of what has been said.

One condition of such cases in particular is strikingly illustrated by it. The organ last affected must generally be one which is apt, from other causes, to be disposed to disease, because, as the debility of the central organs influences all vital organs, the chief effect falls on the weakest part; either that by the nature of our constitutions most exposed to disease, or one that has been rendered so.

The case I refer to was that of a lady who had for many years been exposed to the frequent recurrence of severe irritation of the bowels; yet this state of the bowels depended little on bilious derangement, as it is usually found to do. She did not labour under the symptoms always attending bilious complaints of long standing, and occasional mercurial doses never gave even the temporary relief they usually do in such cases, but only added to the irritable state of the bowels. Her attacks gradually became more frequent, till at length her strength was permanently impaired. In a short time after this she began to cough, which had never been the case at any former period of her life, although she was now between fifty and sixty years of age.

As she was past the time of life when a disposition to pulmonary consumption usually appears, and her family on neither side had been subject to this disease, the cough excited little alarm; but this, like her other symptoms, proved obstinate, and in a very short time after it had attracted serious attention, symptoms indicating diseased structure of the lungs appeared. Her debility was such that she became subject to sudden fits of syncope, and general anasarca supervened. She was now confined to bed, and died of one of the most rapid cases of pulmonary consumption I have witnessed.

The central organs of the vital system had been previously debilitated by the long-continued irritation of the alimentary canal, without any other morbid affection, although the more evident sympathies of this canal are, from its great sensibility, rather with the central organs of the sensitive than those of the vital system. The relations were surprised that a person at her time of life, who had never shown the least disposi-

tion to such a disease, should have been carried off by a more rapid attack of it than they had ever known in any other case.

Here the central organs of the vital system were injured both by the direct effect of the irritation, and sympathetically, by the effect produced on the central organs of the sensitive system by an affection of so extensive and highly sensible an organ, and of such continuance. By the previous disease, the system was in every way prepared for the result when the affection of the lungs supervened: the central organs of both systems had been strained, hence its rapid progress. Can any one doubt that if in this case the irritable state of bowels, which was supposed to be attended with no risk to life, had been relieved, the patient's life would have been saved? Here was a cause gradually and imperceptibly undermining the powers of life, which was thought both by the patient and those she consulted to be of too little consequence to be seriously attended to.

But although long-continued irritation of the bowels, from their great extent and sensibility, must be more or less powerful in slowly undermining the general vital powers, they are much less so than would otherwise be the case, because, although like other vital organs, their function is dependent on the vital organs of the brain and spinal marrow, their sympathy is stronger with the central organs of the sensitive than those of the vital system.

Of all our organs, the liver is the one which partakes most of the affections of the alimentary canal, and in a large proportion of cases supplies the source of many of its most powerful causes of irritation. I have, both in my Treatise on Indigestion and Gulstonian Lectures, entered at length into the proofs of the extensive influence of the liver, although an organ of little sensibility, on the sympathies of our frame; by which, more than any other cause, the consequences of its morbid states are regulated; a circumstance in a great degree depending on the immediate connexion which exists between this organ and the vital organs of the brain,—a connexion far more powerful than exists between any other part and those organs; nor is its influence less remarkable on the central organs of the sensitive system, although it is so ill

supplied with nerves of sensation, arising from the powerful sympathy which exists between the central organs of the two systems, and the direct influence of its affections on the alimentary canal.

Thus it becomes the most fruitful source of the class of diseases we are considering. Owing to its little sensibility, its slighter and more habitual affections are often overlooked, while from its function regulating that of the alimentary canal, their influence is spread over the most extensive and sensitive surface. When to these circumstances its powerful influence on the central organs of the vital system is added, we cannot be surprised at its effects, both in causing and regulating the course of disease.

It is a striking fact, and powerfully illustrates what I am now saying, that in sultry climates, where our sympathies are most, and for the security of health too active, almost all diseases, however they commence, terminate in disease of the liver; and even in temperate climates its general influence on all important diseases may be observed. We never see any serious disease in which its functions are not more or less deranged; but here its affections are less observed, and, if I may so speak, less monopolise disease, because its affections are not, as in sultry climates, disposed to run to deranged structure, and disease of structure is more powerful than that of function, in relieving all concurring diseases.

If these facts be such as here stated, and by the well informed and experienced physician they are too notorious to be questioned,—I say, if such be the facts, and we had understood the nature of the diseases which form the subject of these papers, we might have foretold that the liver must perform an important part in their production; and how amply would such a prediction have been confirmed by actual practice, did my limits admit of it, I could prove by reference to many diseases of the class we are considering. I shall select one of the most important, that of symptomatic pulmonary consumption; for the proneness of the lungs to change of structure often causes their disorganization to be the last in the chain of fatal causes. Many of the observations which I am about to make on this disease are applicable to others.

The circumstances which in pulmo-

nary consumption render the distinction between the original and symptomatic disease doubly important, are, that the former is often a fatal disease from the commencement—so little is the power of our remedies over the affections of the lungs; while in all cases, the latter can be arrested in its early stages, and generally in all stages previous to the structure of the lungs being actually diseased, which in most cases occurs at a later period after the commencement of the functional disease than where it is an idiopathic affection, and that for every case of the original disease in these kingdoms, we meet with many of the symptomatic.

I have said elsewhere, that at least three-fourths of the cases of this disease are of the latter description, but I can truly say that in my own practice, for one case of the idiopathic I have met with at least a dozen of the symptomatic phthisis. It also deserves attention that the latter is that in which the hereditary predisposition is by far the most powerful: I have never in a single instance known many members of the same family fall a sacrifice to the original disease; while I have seen almost whole families swept off by the symptomatic form: that form, although as certainly fatal as the other if the structure of the lungs has been allowed to become seriously diseased, but which, in its early stages, is always curable. A most gratifying proof of which I can adduce, because I have seen in many families, in which one after another had fallen a sacrifice to symptomatic phthisis, its ravages wholly and finally prevented, and that by means of easy application.

It is a striking fact, and shews how essentially different is the nature of these cases, that in the practice of more than thirty years I have never seen the two forms of the disease in the same family. If one of a family labour under either, in any other of the same family seized with it, it will always be found of the same form.

It will appear from what has been said, that it is the functional, not organic, affection of the liver, which lays the foundation of the symptomatic phthisis of which I speak. The organic affection of the liver is too serious a disease to be disregarded; and when, as often happens, it terminates in disordered

structure of the lungs, this disease is to the most careless observer evidently symptomatic.

This circumstance has tended to confirm the error which has prevailed, because, according to a law of our frame which I have had frequent occasion to refer to, the original disease, when only functional, is generally relieved by the secondary disease, even when it also is functional; but when the latter has become structural, it never fails to relieve, and very often wholly removes, the functional disease from which it sprung. From this cause many have been confirmed in their erroneous view of the case, by finding, on examination after death, that the liver bore no marks of disease.

We have a memorable instance of this error in the post-mortem examination of the late Dr. Currie, a man both of talents and correct observation, and who had long laboured under bilious complaints, and regarded all his complaints as originating in them. But those who made the post-mortem examination having reported the liver to be quite sound, but the structure of the lungs destroyed, it has been generally supposed that he had mistaken his own case; he could not have mistaken that he had been long distressed by bilious irritation; and the mistake imputed to him was probably the consequence of the fact just mentioned.

Unless the symptoms of disordered structure of the lungs are unequivocal in the cases we are considering, however in other respects alarming the symptoms, experience has taught me never to despair, unless all morbid distension of the liver having disappeared, it has retired into its proper position under the ribs; for I have in a few instances seen recovery by the means I am about to refer to, where, at first view, the case appeared to be hopeless. But the affection of the liver being completely removed, without having afforded relief to the pulmonary symptoms, I have, as stated in my Treatise on Indigestion, uniformly found a fatal symptom.

It is to be observed, that in such cases the feeling given to the hand by the distended liver is very different from that given by an enlarged liver, the former being much softer and more yielding, and never presenting the defined edge of the latter.

The degree of distention is best ascertained by examining the hepatic region in the erect position, and pressing with the same force on the corresponding part of the left side, and thus determining to what degree the pressure checks the breathing on each side; for in the healthy subject, as I have ascertained both alone and with other physicians, the feeling of the patient is precisely the same on both sides; not even the edge of the liver, in a healthy state, coming below the ribs, and the hand pressing only on the soft bowels on both sides.

The function of many vital organs, particularly those of dull feeling, may be slightly disordered without causing much inconvenience. The vessels of the liver, for example, may be so weakened as to allow of some accumulation of bile taking place in it, so as to cause its edge to descend below the ribs, while the individual still retains the feelings of health; and if the trial be made, such an affection will be found in many, who consider themselves well; this deviation, and even tenderness on pressure in the regions of the pylorus and liver, in a country where bilious complaints so much prevail as in these kingdoms, are by no means uncommon, who cannot be said to be out of health.

But in judging of the tendency in bilious complaints to produce serious disease, the following observation should be constantly kept in view: the more distressing and formidable effects never arise directly from the debilitated state of, and consequent accumulation of bile in, the liver. It is not at all uncommon to find, in two individuals whose livers are equally inactive, and consequently distended, the one declaring that he is in all respects in good health, while the other tells you he is in a constant state of misery from his disease; nay, the liver of the former shall even be more debilitated and distended than that of the latter.

The difference in the two cases consists in the nerves of the one having resisted the cause of irritation, while those of the other are fretted by it; the direct cause of all the more distressing symptoms of bilious complaints. I have had occasion to observe, that in some, the vital organs of the brain and spinal marrow resist causes of nervous irritation more powerfully than in others; and that in some,

after the fret of nerves and general debility becomes permanent, indicating some affection of the central organs, the other vital organs resist the diminished supply of the nervous influence more powerfully than in others: so it happens in the present instance, that in some the nerves resist the impression, made on them by the debilitated state of the organ originally affected, more than in others.

Now until this state of nerves at least temporarily takes place, however much the liver may be loaded, the general health is but little impaired, and the individual will tell you that he is in good health. The slight and temporary effects depending directly on the complaint, he disregards; he is troubled occasionally with some degree of flatulence and acidity of stomach, causing occasional heartburn and some languor of bowels. By easy means these symptoms are relieved, and it is only as the fret of nerves, or a sense of debility caused by the recurrence of the bilious symptoms comes on, and tends to become permanent, that he considers himself an invalid. When, we have seen, this fret of nerves or sense of debility becomes permanent, the central organs of the vital system begin to suffer, and then any of those vital organs, the functions of which depend on the influence supplied by them, and which is from other causes disposed to disease, will feel most the cause which acts equally on all organs of the same description, namely, some tendency to a diminished supply of the influence necessary to their functions; and it is only as this happens that the sufferer comes into danger. Unless these positions be kept in view, neither the nature nor proper treatment of the cases we are considering can be understood.

What are called bilious complaints, while they retain the form expressed by this term, being unattended with danger, and our not being aware that many of our most formidable diseases derive their origin from their continuance,—for did the limits of this paper admit, it could easily be shewn that other diseases of the chest, and many of the most fatal diseases of the head, often derive their origin from the same source,—I say that in consequence of the apparent unimportance of bilious complaints, according to the usual sense of the term, the attention of physicians has

never been directed to them with the care that their effects, when protracted, demand.

Believing that the functions of the nervous system only contribute to those of the sensorial power, they could not be aware that its affections are often the parent of the most formidable diseases, and that, as in the case of the species of pulmonary consumption we have been considering, their removal, which, by the proper treatment, may always be effected, would often be the means of preventing a fatal termination.

It is true that we often see such affections continue for a long life, without producing any of their fatal consequences, owing to the circumstances above stated as depending on peculiarity of constitution; but as it is impossible to foresee what the course of the symptoms will be in any particular individual, the only safe plan is to employ every means in our power in radically removing what are called nervous complaints as soon as our patient applies to us; which, for the most part, they seldom do until the fret of nerve or general debility has become permanent; and then some degree of debility has always been established in the vital organs of the brain and spinal marrow.

Under which circumstances, when the disease makes its next step—that of influencing the function of some other vital organ, by which, according to a law of our frame, to which I have frequently had occasion to refer, the whole force of the disease being diverted from all other organs, is concentrated in one—we are sure to have a disease of difficult treatment, if not of a fatal termination; for we never find even a functional disease, if it arise from previous debility of the central organs of life, yield in the way that original disease of the same organ is found to do; and if this debility has been allowed to remain until it has produced any degree of structural disease in the organ last affected, in which the continuance of functional disease will generally terminate, we shall not, in one case in twenty, prevent a fatal termination. Absolute safety can in no way be obtained but by a removal of the disease in those stages in which we can with almost certainty effect our object.

I shall here, without entering on the particulars of the treatment most successful in confirmed bilious complaints,

for which I beg to refer the reader to the seventh edition of my Treatise on Indigestion, only endeavour to point out the causes which have hitherto rendered the treatment in them so inefficacious; for the usual plan, after a certain degree of relief is afforded, is to tell our patient to attend to the rules of diet we lay down; regulate the bowels by the means we have pointed out, think as little as possible of his complaints, and have recourse to a dose of calomel when he feels more indisposed than usual; and so he is dismissed, an invalid for life. I have said, however, that under such circumstances a cure may almost always be effected. I shall here point out what, as far as I can judge, have been the causes which have prevented the permanent cure, in all cases of long standing, and the principles on which repeated experience has assured me such a cure can almost always be effected.

It appeared that the cause of our failure was, trusting alone to doses of mercury, the only medicine on which we can rely in affections of the liver of however slight a nature, of such amount as could only be given at considerable intervals, that of two or three days, without rendering the effects of the medicine as pernicious as the disease, or more so, in consequence of which the bile always, more or less accumulating, in the interval, in the debilitated liver, and the effect of our doses being thus only temporary, the permanent cure was impossible. Another circumstance which, of itself, would have rendered a permanent cure, in many cases of long standing, impossible, even under the most efficient administration of mercury, is, that we overlooked a consequence of the long continuance of the bilious complaint and the impaired function of the stomach, which generally more or less attends it, the continuance of the irritations of indigestion producing an inflammatory state of the parts most exposed to them, which I found from post-mortem examinations, first takes place in the pylorus, which in those who had long suffered from bilious complaints, was often found as red as if it had been actively inflamed, and spreads more or less to neighbouring parts, and particularly to the left edge of the liver.

This causes a tenderness on pressure, to be felt in the region of those parts, and prevents the proper effects of our

medicines. In the least inflammatory habits this tendency does not always occur; but I can say, from extensive experience, that where it does, which is in a large majority of cases, it obviates the effect of our remedies, and renders the removal of the disease impossible.

With respect to the first of these difficulties, which have rendered our practice, in what is called bilious complaints, if of any standing, so inefficient, it occurred to me, above twenty years ago, that as we cannot give the usual mercurial doses, except at long intervals, during which, in such cases, their effects are in a great degree obviated, some means must be found to maintain these effects during them before we can make effectual progress in removing the disease.

None that I tried had an effect at all to be depended on, till I had recourse to minute doses of mercury, given at intervals of eight hours. The dose I found to answer the purpose was either the twentieth part of a grain of calomel, or half a grain of blue pill, which is equal or nearly equal in power to it. One I have found to suit best one constitution, and the other, another. The minute dose of calomel is most aperient, but on the whole, I have thought that of the blue pill the best alterative.

There are many circumstances to be observed in their employment, which have gradually shown themselves, and many of which are stated in my Treatise on minute doses of mercury. Their good effects, however, are not to be wholly ascribed to their keeping up the effect of the larger dose, which must always be continued under their use, for they have little effect in enabling the liver to discharge the accumulated bile; but in proportion as this becomes less, the larger dose may be employed at longer intervals.

It is a law of our frame, that, although in the sensitive system, every stimulant, however slight, is followed by corresponding exhaustion in the vital system this is only the case with stimulants which exceed a certain power*. Thus it is, that in this system whatever produces the stimulant effect within that range, acts as a tonic. I have found that such is the effect of the minute mercurial dose on the liver.

* Philosophical Transactions for 1596.

While the excitement of the larger dose is followed by a more languid action of the liver, the minute dose supplying a constant and gentle stimulus to the liver within the limit which produces corresponding depression, acts as a tonic, and the organ gradually and uniformly recovers its power under the use of the minute dose, and the whole system, the debility of which depends on that of the liver, experiences a corresponding effect. And I can say, that I am unable to recall one case where there was no disease but the bilious complaint, however long it had lasted, and the patient did not become tired of the means,—for in long-protracted cases the recovery is necessarily slow—in which he was not restored to permanent health; and I can at this moment point out cases which had lasted for twenty years, in which the patient for many years past has enjoyed uninterrupted health.

With respect to the tenderness on pressure of the parts chiefly concerned in the disease, the only means of its removal is blood-letting from the parts in their immediate neighbourhood. The patient is never sensible of this tenderness, as it occasions no uneasiness, except on pressure in its seat; it is therefore always overlooked if the physician does not detect it by an examination of the parts affected; and frequently-repeated local blood-lettings are often required for its removal.

This tenderness is of an inflammatory nature; and although it never assumes the form of active inflammation, it is sufficient to bind up the surfaces, while the object of the treatment is to relax them, and thus to promote a free flow of the secretions; and as our means must always be of the gentlest nature, (for large doses of mercury are capable of causing, and cannot, therefore remove the disease), their effects are easily counteracted. Along with the foregoing means some stomaehic medicine is proper, for grateful as the mercurial is to the liver, to the stomach and bowels it is more or less offensive; but tonics can seldom be employed without injury, and never till all inflammatory tendency is subdued.

Such, with the means of relieving occasional symptoms, which are very various, depending on accidental causes and peculiarity of constitution, is the general outline of the treatment which I have found successful in effectually

removing old bilious complaints, which, although never themselves dangerous in this country, where the liver rarely runs to disorganization, except in drunkards, which has caused too little attention to be paid to them by our profession, are, in the manner above explained, the parent of many of our most important diseases; so that I believe, from very extensive experience, that I speak within bounds when I say, that however slow their progress, they are eventually, in this country, where they may be regarded as the endemic disease, the cause of more deaths than any other, or perhaps of any half dozen of all the diseases we are subject to; for although many constitutions are strong enough to resist their serious effects even for a long life, in a large proportion of cases they run the course which has been described.

It is hardly necessary to add, after what has been said, that their ultimate effects are very various, as they may terminate in a fatal disease of the head, chest, or abdomen, according to the tendencies of the particular constitution, the period of life, and the circumstances in which the individual happens to be placed.

I shall only again remind the reader that, in all serious diseases, we should carefully determine from an examination of the state of the digestive organs, and the history of the case, how far the irritations of these organs have had a share in producing the attack his patient labours under; because if this has been the case, and the disease of those organs, even although in a mitigated form, remains, the removal of the more prominent disease is impossible, unless that in which it has had its origin be detected and removed.

Thus I have found in many acute, and still more in chronic cases, that on examination of the region of the three great digestive organs, the stomach, liver, and duodenum—for when the regular flow of healthy bile languishes, the action of the duodenum becomes imperfect, and the food accumulating in it causes more or less morbid fulness in its region, as well as in that of the liver,—under such circumstances, I say, I have found this examination of as much consequence as that of the pulse, and often more so. For many years I have have never failed to have recourse to it; for even where such affections have no concern in the cause of the disease, they

often, from the extensive sympathies of the liver, supervene in it, and always influence its course, and ought if present to influence the treatment.

If there be any truth in the preceding observations, and they are equally founded in the general laws of our constitution, and extensive experience of actual practice, how erroneous must that treatment be by which all cases of the same disease of the same organ, are often treated in the same way, whether arising from a cause immediately influencing the organ itself, or one which has made its first impression on another part of the system, without correcting the effects of which it is impossible to remove the more prominent disease; for a disease will, *à fortiori*, be supported by the continuance of the cause which produced it. The correctness of this observation is strikingly illustrated by the disease which, on account of its eminence and frequency, I have chosen as an example; even to the degree, I may say, of almost certain safety, instead of quite certain death.

The practical importance of the subject of the preceding part of the present paper has caused it to be prolonged so much beyond what I had intended, that I have left little room for the remaining part, namely, the inferences which necessarily arise from its having been ascertained that the agent employed by the vital organs of the brain and spinal marrow, in all their functions, is voltaic electricity*, for we have seen that it is capable of all those functions; in which, therefore, I shall only attempt the most general observations, referring to the sources of more particular information.

It is reasonable to suppose, that its having been ascertained that a power which we are at all times capable of commanding, and that to any extent that can be required, having been ascertained to be capable of all the functions of the leading power of the vital system, must, if judiciously employed, often be of eminent service in the practical department of our profession; and such has been the result†.

Several circumstances, however, have

hitherto tended to prevent its beneficial effects having been so extensive as it may be hoped they will soon be found to be. New modes of practice, in a profession open to so many proposals which prove of little or no value, the care and anxiety, and in many instances the trouble attending the first trial of means with which we are not familiar, especially if (as in the present case) they require an apparatus which few members of our profession are in the habit of employing, and, above all, if they be such as may do harm instead of good, if not employed judiciously, are, and for the first and last of these reasons, ought to be, cautiously adopted.

I shall close this series of papers by pointing out the chief precautions requisite in the employment of voltaic electricity, which have already been laid before the public in the works just referred to, but have certainly not obtained the attention which is indispensable, even of those by whom this remedy has been most extensively employed,—a circumstance which has greatly tended to confine its employment.

As we might, *à priori*, have inferred, although we can easily direct voltaic electricity to any part in which we know, from the phenomena of disease compared with the results of the experiments referred to in these papers, there is a deficiency of nervous influence, and we always find, from the effects, that deficiency supplied by it; it is not to be supposed that we can supply it precisely in the same way as nature supplies it; or supply it in the exact proportion required, and confine it exactly to those points to which nature confines it.

We find, in consequence, that in addition to the effects we wish to produce, if its application is not cautiously arranged, we obtain at the same time effects that we by no means wish.

All such effects may be ascribed to its tendency to produce an inflammatory state of the parts to which it is applied. I have never in one instance seen this inflammatory state, produced by voltaic electricity, approach to active inflammation; because its beneficial effects may be obtained by the employment of very moderate powers, and I have laid down rules of easy application for confining it within those powers in the cure of diseases, so that there is no risk

* Philosophical Transactions for 1836, and the publications there referred to.

† See my paper in the Philosophical Transactions for 1817, and Gulstonian Lectures for 1835; also Mr. Earle's account of trials made by him in St. Bartholomew's Hospital, in a letter published in the last part of my Treatise on Indigestion.

to life in its employment ; but if it at all excites any degree of the inflammatory tendency, particularly in cases where the disease itself has more or less of this tendency, as is the case in many of the diseases in which its assistance is most called for, we soon find that, with all the precaution we can employ, the use of it cannot, without injury, be continued.

To recur to the case that I have throughout this paper taken as an example. When the disease is in its first stage, that of the bilious complaint, it must not be employed in those cases where any tenderness is perceived on pressure in the region of the pylorus, or liver, or on any part of the alimentary canal, until by local blood-letting this symptom has been removed ; and where it has not existed, care must be taken to examine the regions in question, that we may be assured that it is not produced by the remedy we are employing.

I have found that this precaution is chiefly necessary on first employing it, because when it has succeeded in restoring the due action of the parts, and thus in a great degree removed the irritations attending the disease, it is much less inclined to produce this effect ; which, when it does occur, is always more or less the joint operation of the disease and the remedy.

When the tenderness on pressure occurs under the use of the latter, it must be discontinued, and the tenderness removed by the same means as when it arises from the disease alone, before it is again employed.

With respect to the power of the voltaic electricity employed, I have generally directed that it at first should be no more than causes the patient just to feel it at either of the parts to which the wires are applied, and that it should not be applied for more than ten minutes once in the twenty-four hours ; or, if there is much doubt respecting its effects, in forty-eight hours, its power if necessary being gradually increased, provided no objectionable effects shew themselves. For the cases in which it is most useful, and the particulars of its effects, both favourable and unfavourable, I must refer to the publications above mentioned.

There is one of its effects which was very unexpected, and which, as it has

not been fully stated in any of those publications, I shall here state more fully. It is evident that it may assist the organ to which it is applied in three ways, either by simply supplying the nervous influence where it is defective, in which case its effects are necessarily temporary ; or by exciting the brain or spinal marrow to better action, as far as relates to the diseased part ; or lastly, by restoring to the ganglionic nerves of the part more vigour in conveying their influence to the part in question. Now I have never seen its effects merely temporary, although they are much more so in some cases than in others ; therefore its action must always be more or less by one of the last two means ; but in some cases so small a power has sometimes produced so great an effect, that it can hardly be explained except by supposing that its operation was merely that of giving vigour to the nerves which are its channel of conveyance.

I shall close this paper with a short statement of the most remarkable case of this kind which has ever occurred to me. One of the diseases which it is most powerful in relieving, and for which, as far as I know, we have no other effectual means, is what I have termed in the first publication above referred to, habitual asthma. A lady of about 30 years of age applied to me for the removal of a case of this kind, who had never, even when she was a child, been able to run about with her companions, on account of shortness of breath, as she termed it, which, as she advanced in life, increased so that she could not, when I saw her, even walk up hill without much suffering. I advised no medicine for her, but directed the moderate use of voltaic electricity, which was applied in my presence. In a few minutes she said she breathed with more ease than she remembered ever to have done ; but the most unlooked-for part of the result was, that she never required a second application of the remedy, her breath remaining as free as in the most perfect health, so that she could not only walk, but run up hill, with as much ease as other people.

I have seen some similar instances, in which a few applications of voltaic electricity produced permanent relief, but none so striking. In such cases

I think we must suppose that some obstructing cause in the ganglionic system, as far as it is connected with the organ which is the seat of the disease, had proved sufficient to obstruct its function, though not to affect its structure; for cases of this kind are unattended with danger if unattended with cough. Even a ligature thrown round the eighth pair of nerves materially influences the function of organs supplied by them. If such be the case, the obstruction is of such a nature as may sometimes be relieved by a few slight applications of galvanic electricity; and in almost all cases of this species of asthma*, more or less relief appears to be uniformly its effect, the relief being more or less perfect, and more or less permanent, and not unfrequently final. In the paper just referred to, in the *Philosophical Transactions* for 1817, the result of its employment in about a hundred such cases is given. Most of these were treated in the course of several years, in a public establishment, the County of Worcester Hospital, where the disease among the sedentary manufacturers is of very frequent occurrence, and in the presence of many observers.

I am, sir,

Your obedient servant,

A. P. W. PHILIP.

Cavendish-Square,

OBSERVATIONS ON THE PULSES OF INFANTS.

To the Editor of the Medical Gazette.

SIR,

ON referring to page 190 of the *MEDICAL GAZETTE* for October 28, 1837, I find the following:—

“At the conclusion of Dr. Guy’s paper, Mr. Gorham stated the results of some experiments made by himself on the pulses of infants. These remarks, though *irrelevant* to the paper, were valuable,” &c. &c. By inserting the following communication in the pages of your valuable periodical, you will oblige me, as it will be then rendered evident whether my observations were really *irrelevant* or not, and I shall be enabled to say a few words on a

* Voltaic electricity has little if any effect in removing other forms of asthma which are spasmodic affections, unless they are complicated with habitual asthma, as I have defined it in the publications referred to, which sometimes happens in protracted cases.

subject which has occupied my attention for some years past, although I had not intended to have made any thing public for many to come.—I am, sir,

Your most obedient servant,

J. GORHAM, M.R.C.S.L.

225, High-Street, Borough.
Nov. 1837.

From pretty active obstetric practice during the last five years, it must be imagined that many infants and young children have come before my notice; and for the whole of that time I have been in the habit of collecting divers facts and phenomena which presented themselves. This was done not with a single eye; and the results, some of which are exceedingly interesting, pertain to physiology, and also to the bettering of a prognosis which is proverbially deficient, viz. that in diseases of children.

On ascertaining that a paper was to be read by Dr. Guy, at the Physical Society of Guy’s Hospital, of which I am a member, it occurred to me, that as it purported to treat expressly on the “effect of posture on the pulse,” I might, from the collection I had formed, put together something which should go to illustrate the opinions promulgated in the paper, tending, perhaps, to improve some, or probably to disprove others. After looking through about one half of my books, I was enabled to obtain the results of 150 experiments, made at different times, under varied circumstances and conditions of the infantile state. They were collected with the greatest care, as it was done for my own personal good, in order to assist me in forming a better diagnosis in disease; neither were they obtained in a hurry (five years having elapsed since they were begun), in order to get them finished at any particular period; nor would they have appeared now in such an unfinished state, had it not seemed necessary.

The naked facts of themselves, then, may be relied on: and as I have not time at present to handle them in a manner which I am sure they deserve, in consequence of being engaged in producing a more complete essay on the subject, I trust that a stimulus may be given to others, by their imperfections, to take up a subject which has been very much neglected in this country.

I inclose the tables which were made use of the other evening at Guy’s Hospital.

Y

EXPERIMENTS ON THE PULSES OF 150 INFANTS AND CHILDREN.

TABLE I.—*From Birth to the Age of Twenty-four Hours.*

No.	Age in Hours.	No. of Pulse.	Sex.	Accidental Remarks.
1	12	112	Male.	Length, 19 inches.
2	8	145		
3	7	120		
4	16	128	Male.	
5	24	120	Male.	
6	12	104		
7	12	136		
8	9	116	Female.	Twin—horizontal—waking from sleep.
9	9	136		Twin—horizontal.
10	16	132		
11	24	120		
12	24	100		
13	24	120		
14	24	160		
15	25	104		
16	5 minutes.	120		Counted from funis—horizontal.

Experiments on these sixteen infants, from birth to the age of twenty-four hours, led me to the following conclusions:—

1. The mean number of the pulse of the new-born infant is 123 and a fraction.
2. The maximum number in the above experiments was 160, and the minimum 100.
3. The mean number of three, who were stated in the table as being in the horizontal posture (for I believe all were horizontal, although I cannot aver this for a fact), was 124.
4. The average number of the pulse of three male infants, taken from the above experiments, was 120.
5. The pulse of one twin female was 116.

My first conclusion is derived from facts, without any allusion to the posture, the state of motion or rest, or muscular exertion. Neither do I know of any author who has noticed these particulars as regards the infantile state, and as connected with the pulse. My third conclusion is derived from three experiments: a scanty number, truly; yet more, indeed, than has been made by any one else, according to my reading. It will be seen at once that it relates to

posture, and also to the pulse: it bears, in fact, immediately on the subject of the *effect of posture on the pulse*, and is irrelevant to a paper read actually on the very subject! (?).

From the table it will also be learned, that the pulse of the infant, at this early age, is slow; and it does, indeed, acquire frequency up to a certain period, which will be mentioned and better understood when the following tables have been considered.

Also, that although all the observations that have been hitherto made on the pulse of the infants are not without their value, yet that they are rendered imperfect and susceptible of improvement, by taking into consideration the circumstances of posture, and laws emanating therefrom, mentioned in the extremely valuable paper of Dr. Guy.

As regards the postures, it is impossible, indeed, to obtain some on which we may wish to experiment in these young creatures. Is it likely, for instance, to find little Sampsons at birth, who should be able to retain themselves in the erect position by their own muscular effort, unaided by any external support for one moment? Now as “the effect of posture forms merely a particular case of the general law—viz.

that muscular contraction, whether employed to change the position or to maintain it in the same position, accelerates the pulse," it will be evident that, although experiments can be made, and easily too, in this particular posture in the adult, yet that in no instance have they ever been made, nor, indeed, can be, on the infant a day old: and the same observation will apply to the sitting posture.

It should be expected then, according to a law which emanates from that of Dr. Guy, that the pulse of the infant should be slower *now* than afterwards,

in consequence of the relaxed and usual horizontal position of their bodies; and this is actually the case from my experiments. Dr. Guy states it as matter of fact, that "the effect produced by change of posture on the pulse is in both sexes and *in all ages* considerable." The Doctor certainly could not have made this statement, "including all ages," from actual experiment, inasmuch as it is a physical impossibility to place an infant in the erect position, under the proviso enacted by Dr. Guy—that muscular action shall sustain and keep it there.

TABLE II.—*From One Day to One Week Old.*

No.	Age.	No. of Pulse.	Sex.	Accidental Remarks.
1	40 hours	120	female.	
2	78 "	120		
3	30 "	136		
4	4 days	120	male.	
5	6 "	96—112		Asleep.
6	4 "	148	female.	Taken from heart.
7	2 "	112		
8	36 hours	136		
9	7 days	128	male.	Stout.
10	6 "	132	male.	
11	not a week	152	male.	Taken from heart.
12	do.	112		
13	do.	130	female.	
14	do.	132	male.	
15	do.	108	male.	
16	do.	140	male.	Taken from heart.
17	do.	160	male.	
18	39 hours.	128		
19	2 days.	112		Asleep.
20	6 days.	152	female.	
21	47 hours.	120	male.	
22	5 days.	120		
23	6 "	136		
24	3 "	128		
25	7 "	112		
26	6 "	152		
27	46 hours.	110		
28	5 days.	126	male.	
29	3 "	124	female.	
30	under a week.	120	female.	
31	do.	120	male.	
32	do.	136	male.	
33	do.	130	male.	
34	do.	108	male.	
35	do.	128	female.	
36	do.	120	male.	
37	do.	136	male.	
38	do.	140	male.	
39	do.	128	female.	
40	do.	146	female.	
41	do.	132	female.	
42	2 days.	120	female.	Horizontal ; 22 inches long.

We do not, indeed, deny that the erect position does not cause an acceleration of the pulse in the new-born infant; but we assert, that if such be the case, then another cause must be assigned for this frequency besides muscular contraction.

These experiments on 42 infants, from one day to one week old, led me to the following conclusions:

1. The mean pulse of the infant between the age of 1 day and 1 week is 128.

2. The maximum in the above experiments is 160, the minimum 96.

3. The pulse of one female in the horizontal posture (although most of them were probably in the horizontal posture, yet it is not stated in the table, and must not, therefore, be given as a fact) was 120.

4. The mean number taken from eleven females is 131.71.

5. The mean number taken from nineteen males is 122. From four and

TABLE III.—*From One Week to One Month Old.*

No.	Age in Days.	No. of Pulse.	Sex.	Accidental Remarks.
1	11	108	Female.	Twin—position horizontal.
2	11	108		Twin—position horizontal.
3	18	176		Sucking.
4	9	146		
5	15	108	Male.	
6	12	148	Female.	Counted from heart.
7	9	140		
8	28	120		
9	11	152	Male.	
10	15	128		Dozing—horizontal.
11	27	152	Female.	Counted from heart.
12	10	156	Male.	
13	9	108	Male.	
14	10	116	Female.	
15	14	132-120	Female.	
16	21	144		
17	8	128		
18	10	168		
19	14	144	Female.	
20	11	128		
21	9	120		
22	9	156		
23	21	140		
24	15	104		Asleep—horizontal.
25	10	120		Asleep—horizontal.
26	28	140		Asleep—horizontal.
27	20	140		Sucking.
28	12	148		
29	18	152		Dozing—horizontal.
30	8	128	Male.	
31	19	140	Female.	Sleepy—horizontal; length 22 inches.

five it results that the pulse of females is much more frequent than that of males.

6. The average of three experiments on children asleep, and in the horizontal posture, is 108.

7. The pulse is quicker during the first week than during the first day.

8. The pulse is slower during the first week than it is found to be afterwards.

Infants at this age also cannot stand or sit upright, unsupported.

From One Day to One Month Old.

From the second and third tables, which together include experiments on 73 infants, it results—that the pulse in the infant from one day to one month old, is 131.

Remarks on Table III.

These experiments led to the following conclusions:

1. The mean number of the pulse in the infant from one week to one month old, is 135.45.

2. The maximum in the above table is 176, and the minimum 104.

3. The mean, from experiments on eight in the *horizontal* position, is 125: the mean of two of them which were asleep being 122, and of two which were twins, and not asleep, 108.

4. The mean, from experiments on six females, is 141.67.

5. The mean, from experiments on five females, is 130. From five and six it results that the pulse is quicker in females than in males.

TABLE IV.—*From One to Five Months Old.*

No.	Age, in Days.	No. of Pulse.	Sex.	Accidental Remarks.
1	70	160		Asleep.
2	30	104		Asleep.
3	42	136		
4	148	112		No teeth—lower gums rounding.
5	30	152		
6	126	128		Sitting.
7	39	130		
8	42	140		
9	49	140		
10	98	156		
11	35	160		Asleep.
12	112	156		Sitting—stout— $22\frac{5}{8}$ inches long.
13	49	136		Asleep—horizontal—premature.
		160		Awake—horizontal.
		160		Sucking—semirecumbent.
		176		Sucking—semirecumbent.
14	126	116		Twenty-four inches in length.
15	84	136		Sucking—semirecumbent— $22\frac{1}{2}$ inches long.

These experiments allowed me to draw the following conclusions:—

1. The mean pulse of the infant from one to five months old is 148.85.

2. The maximum number in the above experiments is 176, and the minimum 104.

3. The mean of five, which were in the *horizontal* posture, is 144; and of these,

four were asleep, the mean number of the pulse being 140.

4. The mean of five, in the semi-recumbent position, is 151.20; and of these, three were sucking.

5. The pulse is much more frequent after the first month than before it; and this frequency increases up to a certain period.

TABLE V.—*From Five Months to Two Years Old.*

No.	Age, in Months.	No. of Pulse.	Sex.	Accidental Remarks.
1	24	100-118		
2	5½	144		Asleep—horizontal—9 A.M.
3	12	120		Eight teeth.
4	14	136		Five teeth.
5	14	120		Asleep—horizontal.
6	13	120		
7	19	130		
8	21	136		Sitting.
9	14	124		Standing.
10	15	136		Sitting.
11	16	108		Horizontal—asleep.
12	13	133		Standing—30 inches long.
13	16	112		Asleep—two teeth only—horizontal.
14	8½	148		Asleep—horizontal.
15	6	128		Standing.
16	7½	148		Sitting—seven teeth—24 inches long.
17	12	132		Sitting—two teeth—25½ inches long.
18	11	158		Sitting—two teeth—25½ inches long.
19	6	128		Semirecumbent.

TABLE VI.—*From Two to Four Years Old.*

No.	Age in Months.	No. of Pulse.	Sex.	Accidental Remarks.
1	34	96		Asleep—horizontal.
2	39	124		Standing.
3	35	92		Asleep—horizontal.
4	36	108		
5	47	104		Asleep—horizontal.
6	40	116		Asleep—horizontal.
7	30	124		Standing—32 inches long.
8	36	108		
9	36	120		
10	48	120		
11	29	120		
12	36	108		Standing.
13	48	116		Standing.
14	36	120		Sitting.

Remarks on Table V.

These experiments on nineteen children led to the following results:—

1. The mean pulse of the child, from the fifth month to the second year, is 130.

2. The maximum from these experiments is 158, and the minimum 100.

3. The mean of five experiments, in which the children were in the horizontal position and fast asleep, is 126.40.

4. The mean of five experiments, in which the children were sitting, is 142.

5. The mean of three experiments, in which the children were standing, is 128.33.

6. The pulse at this age, which embraces the teething period, is quicker than at birth.

Remarks on Table VI.

From these experiments on fourteen children I draw the following conclusions:—

1. The mean pulse in the child from two to four years old, is 112.56.

2. The maximum number in the experiments is 124, and the minimum 92.

3. The mean of four, who were in the horizontal position and asleep, is 102.

4. The mean of four who were standing, is 118.

5. The number of one who was sitting, is 120.

6. The pulse at this age, which has passed the teething period, is much slower; and from this time it gradually diminishes in frequency to the end of life.

TABLE VII.—*From Four to Ten Years.*

No.	Age in Years.	No. of Pulse.	Sex.	Accidental Remarks.
1	7	88		Horizontal.
2	5	100		Horizontal.
3	4½	100		Standing.
4	5	100		Sitting.
5	5½	100		Horizontal—asleep.
6	7	128		Horizontal—now awaking.
7	10	104		Horizontal.
8	5	120		Standing.
9	4½	133		Standing.
10	5	124		Sitting.
11	7	{ 92		Standing.
		{ 92		Sitting.
12	9	100		Standing.
13	5	{ 116		Standing.
		{ 104		Sitting.

These experiments on thirteen children lead me to infer, that—

1. The mean pulse in the child between the fourth and tenth year, is 107.63.

2. The maximum in the above table is 133, and the minimum 88.

3. The mean of five experiments on those in the horizontal position, is 104.

4. The mean of six experiments on those who were standing, is 110.17.

5. The mean of four experiments on those who were sitting, is 107.50.

6. The pulse is slow in the horizontal posture. It acquires frequency if this be changed to a sitting, and becomes still more frequent in the erect position.

60 Experiments relating to posture as connected with the pulse in infancy and childhood.			

If the foregoing tables, and particularly the last, which is only, indeed, a recapitulation from parts of them, relate to the effect of posture on the pulse, then it were well that those gentlemen to whom it is entrusted to make public the discussions which emanate from the Physical Society of Guy's Hospital,

should look before they leap. If, on the other hand, they do not relate (?) to the effect of posture on the pulse, still they are valuable, and serve in a small degree to fill up a deficiency which always exists in works on physiology—viz. original facts and observations on the infantile condition.

REMARKS
ON
THE NATURE AND TREATMENT
OF THE
DIFFERENT FORMS OF PORRIGO.
By WALTER DICK, M.D.

THERE are some writers, and amongst them the Baron Alibert, who wish to have the names of cutaneous diseases descriptive of one or more of the prominent characters or symptoms of these diseases; in other words, to have the sign significant of the thing signified.

But the diseases of the skin are so numerous, and many of them differ so little from one another, that we cannot anticipate much success for such a proposal. Here, as in other departments of science, we are inclined to think that attempts at descriptive terminology will generally prove unsuccessful, and tend perhaps to retard, rather than to advance the progress of knowledge. In dermatology what is especially necessary is uniformity in the use of terms; no matter whether these terms be arbitrary, or not descriptive of any prominent characters of the diseases to which they are given.

The indeterminate manner in which the names of cutaneous diseases have been used, has unquestionably tended greatly to impede the progress of cutaneous pathology, and hence we ought at present to be anxious to fix the acceptance of terms already in use—to establish, by careful observation and faithful description, the diseases to which each of these terms ought to be restricted, rather than to be coining new terms. By and by, as our knowledge of skin diseases increases, it will perhaps be requisite to reform and simplify the cutaneous nomenclature, and we hope the time is not very distant when we will be enabled to construct a nomenclature of these diseases, taking from their seat, or the organs in which they originate, generic terms, and particularising the subordinate varieties by appropriate epithets. But till once we are enabled thus effectually to reform the nomenclature and arrangement of skin diseases, let us adhere to the terms hitherto in use, and labour to be unanimous as to the number, external characters, and seat of the morbid appearances of the cutaneous tissue.

Porrigo and tinea capitis are terms used synonymously by writers, but the acceptance of either is not yet very definite, nor is their derivation calculated to lead us to bestow either term on any particular group of eruptions. The term tinea came into use some time before the revival of letters, and was bestowed by writers on several eruptions of the scalp bearing more or less resemblance to one another. Lorry thinks it is a corruption of the Arabic word *alvathim*, by which Avicenna designated the humour which he supposed produced porriginous affections. “A quo nomine (alvathim) barbari ut videtur thim et thineum et tineam fecerunt*.” Another, and I think a more plausible opinion, respecting the origin of the term tinea, is that of Mercurialis, who supposed that it was bestowed on certain eruptions of the scalp, from some fancied resemblance which they bore to the ravages of moths, or tineæ, on certain substances. But it seems as probable that erroneous pathological views gave rise to the term in question, and that it originated from a belief in certain minute insects, or tineæ, being the proximate cause of the eruptions to which it was given, rather than from

their resemblance to the ravages of moths. Indeed, we find a writer not only broaching this view of porriginous eruptions, but actually describing the appearance of the insects which he supposed were the cause of them. “Sennertus,” says Turner, “hath often seen them, and been consulted by way of prescription to destroy them*.” What Sennertus took for insects were probably neither more nor less than *nits*, as they are vulgarly called, or the remains of the ova of pediculi,—a class of parasites neither very scarce nor barren on the heads of many individuals.

Since the promulgation of Willan's classical nomenclature of eruptive diseases, the term tinea has been but seldom used in this country. Willan rejected it as a word not sanctioned by ancient usage, and adopted its synonym, porrigo, which, as Bateman remarks, he uses nearly in the same sense in which it was used by Celsus, who bestowed it on the moist and ulcerating, as well as the furfuraceous, eruptions of the scalp.

Considerable difference is still to be met with in books respecting the number of species that ought to be ranked under the generic term, porrigo. That a culpable laxity of diagnosis leads many to range eruptions under that term, which, strictly speaking, are not at all entitled to it, every one who has seen any thing of cutaneous practice will readily admit. By several practitioners and different writers, almost every eruption which attacks the scalp is indiscriminately classed as a porriginous disease. Willan himself is, to a certain extent, chargeable with this error. The eruptions which he has arranged under the generic term porrigo, are very dissimilar in their nature and external appearance. While some of them, such as those eruptions so common in young children, and known by the name of porrigo larvalis, crusta lactea, or milk scall, are generally of a salutary tendency, and may be considered as efforts of the system to obviate more serious diseases, others are more strictly local in their origin, and in place of being salutary, harass the patients during a long period, bidding defiance too often to the best-directed efforts for their cure, and when cured not unfrequently leaving behind them permanent deformity in the shape of in-

* Lorry, de Morbis Cutaneis, p. 463.

* Turner, de Morb. Cut. p. 136.

curable alopecia, or baldness, to a greater or less extent.

In place, then, of keeping diseases so dissimilar in their nature in the same genus, it would be better I think to draw a line of distinction between them, and refer them to different genera, as we may be warranted in doing. That the porrigo larvalis and porrigo favosa of Willan are diseases very different from the other forms of porrigo described by the same author, and infinitely less rebellious in general to remedial treatment, few, who have paid particular attention to eruptive diseases, will deny: and that the two forms of eruption just specified would be more correctly placed in the genus impetigo, than in that of porrigo, is an opinion which is now beginning to be pretty generally admitted.

Bateman, who adopted Willan's arrangement and nomenclature of porriginous diseases, in deference to his illustrious preceptor, and in order to avoid the confusion of altered arrangement, nevertheless observes, "That experience has led me to question altogether the propriety with which Dr. Willan classed the crusta lactea under the genus porrigo, and to believe that impetigo larvalis would have been the more correct appellation." The porrigo favosa of Willan seems likewise to be a variety merely of impetigo affecting the scalp. The pustules which it exhibits are, psudracia, and the discharge which they pour out when ruptured, is very similar to that furnished by the other forms of impetigo*. Referring, then, these two eruptions to the genus impetigo, we have remaining Porrigo furfurans—P. lupinosa—P. scutulata—P. decalvans: four forms of cutaneous lesion alone entitled to be ranked as true porriginous affections.

In Alibert's new classification, his group of porriginous diseases ("dermatoses teigneuses") consists of three genera.

Genus.	Species
1. <i>Achor</i>	{ <i>Lactuminosus</i> . <i>Mucidiuus</i> .
2. <i>Porrigo</i>	{ <i>Furfuracea</i> . <i>Amiantacea</i> . <i>Granulata</i> . <i>Tonsoria</i> .

3. *Favus* { *Vulgaris*.
 { *Scutiformis*.

However ingeniously Alibert may argue in favour of ranking the above-mentioned eruptions together—however acute he may be in seeing the affinities which they possess, and which entitle them, in his estimation, to form together "one natural group"—we can see no reason for his referring the genus, *achor* and *porrigo granulata*, to the "dermatoses teigneuses," rather than to the "dermatoses eczematueuses," except that they, like the true porriginous eruptions, appear ordinarily on the scalp. The region of the body, then, on which they appear, seems to us to be the bond of union between Alibert's dermatoses teigneuses. He, however, observes, "les diverses teignes ont des phénomènes communs, qui considérés d'une manière générale doivent les rattacher au même groupe dans la grande famille des dermatoses; tels sont l'irritation plus ou moins vive de cuir chevelu, son état hyperhémique, le prurit, une sorte de douleur tensive, et plus ou moins prononcée, selon quelles pénètrent plus avant dans l'épaisseur du derme*."

We nevertheless are of opinion that Alibert has approximated eruptions which have really no great claim to be ranked together; and in place of simplifying, he has rendered more intricate the study of porriginous eruptions, by his confused arrangement, and the introduction of new terms.

M. Bielt is of opinion that the species belonging to the genus porrigo may be reduced to two—the porrigo lupinosa and P. scutulata. In this opinion he comes pretty near Lorry, who affirms that the only disease entitled to the term tinea is the disease known at present by the name of porrigo lupinosa. Bielt, Rayer, and others, maintain that the eruption denominated porrigo furfurans is not referrible to porrigo, being always, as they assert, either eczema attacking the scalp, or pityriasis. That eczema is often mistaken for a porriginous affection, we very readily admit; but we are at the same time firmly persuaded, that the above-named pathologists have committed a great, and to us incomprehensible mistake, in denying the existence of Willan's furfuraceous porrigo. It is the form of porrigo most commonly met with in this country, and it is

* Dr. Burns, whose opinion is entitled to great deference, observes "that porrigo favosa is a mere variety of porrigo larvalis," or, as it ought rather to be called, impetigo larvalis, "differing in nothing except in the pustules being a little larger."—*Burns' Midwifery*, p. 595.

* *Monographie des Dermatoses*, tom. i. p. 426.

in general exceedingly difficult of cure. We would hence have supposed that it would have forced itself upon the attention of the most careless observer. From its spreading through families into which it has been introduced, and from being occasionally produced by the other forms of porrigo, we are surely warranted in ranking it as a porriginous affection. It is to this disease that the popular term Ringworm is most frequently given*. We admit, however, contrary to the opinion of Willan and Bateman, that the elementary form of the eruption is not pustular, and hence objections may be most justly started against placing it in the genus porrigo. Yet notwithstanding the apparent inconsistency of classing a non-pustular eruption with others of a pustular character, it is proper, I think, considering its affinity to the other forms of porrigo, to suffer it to remain where Willan and Bateman have placed it.

Plenck, from observing that the different species of porrigo appeared with different elementary lesions, was led to rank them in no less than three different orders, viz. Squamæ—Crustæ—Morbi Pileorum. Thus, in his little work, entitled "*Doctrina de Morbis Cutaneis*," we find several eruptions of the scalp under the terms tinea and scabies capitis, amongst the crustæ. We find nearly the same diseases, under the term porrigo, amongst the squamæ. Lastly, porrigo decalvans, or, as Plenck calls it, alopecia areata, is met with amongst the morbi pileorum. Admitting (as we must) that there is a difference in the elementary appearance of the several eruptions included under the term porrigo, it is, nevertheless, we think, an unnatural and unnecessary proceeding to separate, so widely as Plenck has done, diseases in other respects having many points of resemblance. Such a proceeding would prove highly disadvantageous.

* We are quite aware that it is the *P. scutulata* of Willan that is deemed, by the majority of medical practitioners, "ringworm." We shall afterwards prove, however, that it is the *P. furfurans* which is, by non-professional people, reckoned ringworm, a disease which is beheld with much alarm and regret by well-informed parents, when it appears within the family circle. They are aware of its inveteracy. It is a disease, moreover, which is better known by many out of the profession than by some practitioners. We shall afterwards state our reasons for thinking that *P. scutulata* is a term which might, with every propriety, be expunged from the cutaneous nomenclature.

Taking contagion, difficulty of cure, and alteration of the appearance of the hair, as the most striking features of the genus porrigo, we may place in it, without reference to their elementary forms, the *P. lupinosa*, the *P. scutulata*, the *P. scutulata*, the *P. furfurans*, and the *P. decalvans*.

By observation and reflection we have been led to believe that the organs attacked by porrigo are the sebaceous glands and structure secreting the hair. The connexion between these two structures is so intimate that they must act and re-act upon each other. From this consideration some light is thrown upon the symptoms of the disease in question. In porrigo lupinosa, for example, the sebaceous follicles are the organs primarily affected, and from the intimate connexion between these organs and the structure producing the hair, the latter is very apt to suffer. It is from this communication of disease from the one structure to the other, that the hair so generally and so speedily becomes altered in appearance in this form of porrigo; and the incurable alopecia, which it not unfrequently causes, results from the disease destroying both the follicles and structure secreting the hair. In porrigo furfurans (true ringworm) the disease originates in the structure producing the hair, and from the reverse of what occurs in *P. lupinosa*, the sebaceous follicles may become secondarily affected, and produce an irregular pustular crop scattered over the furfureous patches.

It is not long since Alibert remarked, "Que trouve-t-on dans les auteurs touchant la nature et le caractère spécifique des teignes? Des renseignements incertains, des dissertations vaines, des détails vagues*." Since then some important light has been thrown on some of these very interesting forms of cutaneous disease. Much, however, yet remains for further investigation.

In the preceding remarks we have endeavoured to establish the forms of disease strictly referrible to the genus porrigo—a task by no means so unimportant as some may be inclined to think.

Respecting the number and specific names of the eruptions referrible to porrigo, much difference of opinion is ob-

servable in the writings of French and British dermatologists; and a considerable step in the progress of improvement will have been made, when uniformity on their topics is manifested by the profession profession at large, in this and other countries.

In admitting the existence of four forms of porriginous disease, we beg to remark, that we believe these four species originate in but two different structures or sets of organs, so that we are inclined to think that porriginous eruptions might be reduced to two, viz porrigo originating in the sebaceous glands, and porrigo originating in the structure producing the hair. These opinions may be premature or incorrect; let observation confirm or confute them.

[To be continued.]

PUNCTURATION IN ASCITES.

To the Editor of the Medical Gazette.

SIR,

THE patient treated for ascites by puncturation, of whom there appeared some account in the number of your journal of the 7th ultimo, has continued to improve in health, and is now nearly well. That account extends to the 25th of September last, at which period I had made thirty-eight punctures, and obtained a reduction of four inches in the circumference of the abdomen, with alleviation of the urgent symptoms, and marked amendment of the general health of the patient. Thirty-three punctures have been made since that time: in September, two on the 26th, two on the 29th, and five on the 30th; in October, two on the 2d, two on the 4th, two on the 5th, one on the 10th, one on the 11th, one on the 13th, one on the 16th, one on the 18th, two on the 20th, two on the 22d, one on the 24th, two on the 26th, and three on the 30th; in November, one on the 3d, one on the 6th, one on the 11th, and one this day. Their mode of action appears to be this:—the fluid, with the exception of a small quantity which escapes through the opening in the skin, oozes for three or four hours from the cavity of the peritoneum into the subcutaneous cellular tissue, which it loads and oedematizes. From hence

it is gradually absorbed, and chiefly during the next 5 or 6 hours; after which the patient voids a good deal of urine, and often perspires pretty freely. This process appears to be continued or repeated more or less completely, until the peritoneal orifices of the punctures close. Thus has the patient been relieved of the greater part of the fluid which the peritoneum contained. He is now almost restored to health. The circumference of his abdomen is now only three feet four inches, being one foot four inches less than when the operation was first performed: his pulse is at seventy-two, his breathing free; the muscles have regained firmness and strength, and he is beginning to resume his occupations as a surveyor. His tongue is still rather red at its margin, and smooth on the surface, but the appetite is good, and the stools are natural. The urine appears to be of good quality; it is frequently abundant, and then rather pale and aqueous.

The punctures were performed nearly on a level with the umbilicus, with the exception of eight or ten made three or four inches above it: about one-third of them were made in the linea alba, and the others on either side, and within a distance of this line varying from four to eight inches. With regard to their number and the days on which they were practised, I was guided somewhat by the effect they produced on the disease and on the patient. As they sometimes left a little soreness, and I found latterly a small number answer as well as more, I made the fewest requisite. The soreness, and occasionally the indisposition of the patient, sometimes induced me to make them less frequently than every other day, which, however, upon the whole, seemed to me to leave the fittest intervening time from one operation to another.

During this treatment the diuretics and blue pill, previously administered by Mr. L'Estrange and myself, have been discontinued. We have given only potas. nitrat. gr. xii. thrice a day, with whey and parsley tea.

I remain, sir,
Your obedient servant,

THOMAS KING.

6, Maddox-Street,
Nov. 13, 1837.

LUNATIC ASYLUMS.

To the Editor of the Medical Gazette.

SIR,

YOUR observations on the "Regulation of Lunatic Asylums" are judicious and humane; for although much has been effected to improve the management of the insane since the existence of the flagrant instances of abuse which you quote, it is to be feared that much still remains to be done. To assist in such improvement has been the great object of my professional life, and I trust that my efforts have not been altogether unavailing. Unwilling, however, to thrust myself on public notice, I should not now have addressed you but for an expression in your remarks which has been misinterpreted to my disadvantage, and which, as it is evidently unintentional on your part, I feel confident you will permit me to explain.

In page 135 you say, "In a Wiltshire madhouse, Dr. Fowler found a man confined in an oblong trough, chained down;" and you then copy a part of Dr. Fowler's evidence. You do not, however, as Dr. Fowler did, mention the name of the house; and as this is the oldest asylum in Wiltshire, and as Dr. Fowler has been for more than twenty years the physician appointed by law to visit here, the observation has been erroneously supposed to point at this house. You are aware that the slightest breath is sufficient to taint the purest reputation, and you will not wonder at my earnest desire to correct so groundless a mistake; and the rather, that the Minutes of Evidence before the Select Committee of the House of Commons, from whence the extract is made, contain many flattering testimonies on the conduct of this asylum, and that Dr. Fowler himself stated that Laverstock House was the best private asylum he had ever seen. This good opinion, I have reason to believe, has never been forfeited.

Whilst I am upon the subject, I would remind you that the legislature formerly sanctioned the ignorant and barbarous treatment of lunatics to which you allude; for an act of parliament, which has not been repealed many years, actually authorised the confinement of lunatics in asylums, "there to be chained and beaten if necessary!"

And to shew you that such practices exist even now *out of* asylums, it is not long since, that, on the arrival of a patient here, the person who brought him counselled my partner, Mr. Lacy, to shew the patient a whip if he was refractory, for that he was always better after a good horsewhipping!" Every day's experience, indeed, shews me how little the kind and true management of the insane is understood, where they are under the care of relations or mere keepers; and as I am willing to hope that great improvements have taken place in most lunatic asylums, I entertain the firmest conviction that no management can be so perfect and effectual as may be found in the best establishments of that kind.

Your "strongest instance" to prove the necessity of better regulations in licensed houses—namely, the "Willis Moseley" case—is scarcely available as an argument; because in that case there was no licenser, and consequently no visitations.

With respect to the proportion of cures at the Middlesex Lunatic Asylum being less than the acknowledged excellence of its arrangements may lead you to expect, it should be borne in mind, that as the house was quickly filled with pauper lunatics, brought from all parts of the country, many of them were old cases, long established as incurables. To illustrate this remark, I would mention the result of practice at Laverstock, transmitted some time ago to the Lord Chancellor, in conformity with his instructions.

* Of every 100 patients admitted here, within three months from the first attack of insanity, there were cured 88.

Of every 100 admitted whose disease had existed more than three months, and not exceeding five years, there were cured 45.

Of every 100 admitted whose insanity had been existing more than five years, there were cured only 12.

The number of patients here, under restraint, does not exceed $2\frac{1}{2}$ per cent.; and the number of deaths, including periods of cholera and influenza, is not more than 5 per cent.

I have been led on farther than I in-

* A similar return from the York Retreat states the number cured in this class to be 87; and Capt. Basil Hall states a similar return from the best American asylum to be 89.

tended, and fear that I have intruded too much on your space; but the subject is one which deeply interests me, and if I can see my way clearly to a point where legislative enactment may, without cramping and fettering the energies of honourable practitioners, effectually guard the unhappy objects of its care from ignorance and brutality, I shall indeed rejoice; but there are a thousand considerations which arise, too important to be dispatched hastily, and which require the most cautious examination. The cure is as much an object of anxious attention as the care of lunatics; and after all that can be accomplished by mere law, much must necessarily depend on the skill, feeling, and integrity of those who have the conduct of asylums.—I am, sir,

Your very obedient servant,

W. FINCH, M.D. F.L.S.

Laverstock House, Wilts,
Nov. 13, 1837.

SIR DAVID BREWSTER ON PRESBYOPIA AND CATARACT.

To the Editor of the Medical Gazette.

SIR,

SOME years ago, my attention was attracted by the following remarks from the pen of Sir David Brewster*.

"There is a change which takes place in the human crystalline lens, between the age of 30 and 50, when the person begins to experience slight difficulties in reading small type or ill-printed books, particularly with candle light. This imperfection of vision, at first very slight, and scarcely appreciable, arises from a mechanical change in the condition of the lens, by which its density and refractive power, as well as its form, are altered. This change is analogous to that which takes place in every other part of the human frame on the approach of age. It commences in general, not uniformly throughout the whole lens, but in particular parts of it; most frequently at the margin of the lens, and is often accompanied by a partial separation of the fibres and laminae of which it is composed.

"If the human eye is not managed with peculiar care at this period, the

change in the condition of the lens often runs into a cataract, or terminates in a derangement of fibres, which, though not indicated by white opacity, occasions imperfections of vision that are often mistaken for amaurosis and other diseases. A skilful oculist, who thoroughly understands the structure of the eye and all its optical functions, would have no difficulty, by means of nice experiments, in detecting the very portion of the lens where this change has taken place; in determining the nature and magnitude of the change which is going on; in applying the proper remedies for stopping its progress; and in ascertaining whether it has advanced to such a state that aid can be obtained from convex or concave lenses. In such cases lenses are often resorted to before the crystalline lens has suffered an uniform change of figure or of density; and the use of them cannot fail to aggravate the very evils which they are intended to remedy. In diseases of the lens where the separation of fibres is confined to a small spot, but is yet of such a magnitude as to give separate coloured images of a luminous object, or irregular haloes, it is often necessary to limit the aperture of the spectacles, so as to allow vision to be performed by the good part of the crystalline lens."

Similar remarks, with part of the above as an extract, are to be found in Sir David Brewster's Treatise on Optics, p. 302. Speaking of long-sightedness, he observes, that the change in the state of the crystalline upon which it depends "frequently begins at the margin of the lens, and takes several months to go round it."

As it is not readily to be supposed that a philosopher of Brewster's patient turn of mind and profound knowledge would throw out any hasty or ill-founded observations on so important a subject, it is to be regretted that the learned author has not been somewhat more explicit in the statements he has made in the above passages. Many of your readers, I think, would consider it desirable to be favoured with answers to the following queries.

1. How has it been ascertained that the change on which presbyopia depends commences in general, not uniformly throughout the whole lens, but in particular parts of it, and most frequently at its margin?

* Edin. Encyclop. vol. xv. p. 623.

2. How has it been ascertained that this change is often accompanied by a partial separation of the fibres and laminae of which the lens is composed.

3. What is the evidence that mismanagement of the eye at the period when presbyopia commences, often causes that change to run into a cataract, or to terminate in a derangement of fibres, occasioning imperfect vision that are often mistaken for amaurosis and other diseases?

4. What are the nice experiments by which it is so easy to detect the very portion of the lens where this change has taken place, and to determine the nature and magnitude of the change which is going on?

5. What are the proper remedies for stopping the progress of this change, which the skilful oculist would have no difficulty in applying?

6. Is it common for those in whom the presbyopic change is advancing, to complain of seeing coloured images of luminous objects, or irregular haloes of light?

7. On the supposition that they are affected in the way just mentioned, will limiting the aperture of the spectacles really prevent vision by the disordered portion of the crystalline lens?

8. On the supposition that limiting the aperture of the spectacles allows vision to be performed only by the good part of the crystalline, will the continued use of such spectacles be followed by any permanent advantage?

These queries may not fall under the notice of Sir David Brewster: if they do, I should hope that he would honour them with a few sentences of explanation. Perhaps some of your numerous readers may have directed their attention to the same subject, and may take an opportunity, through the medium of your widely circulated pages, to give their views upon it to the public.

I am, sir,

Your obedient servant,
A STUDENT OF THE EYE.

Glasgow, Oct. 18, 1837.

[We shall take care that this is brought under the notice of Sir David, and shall be happy to insert any answer to our intelligent correspondent with which he may favour us.—*Ed. Gaz.*]

SINGULAR NERVOUS ATTACK.

To the Editor of the Medical Gazette.

SIR,

If you deem the following case worthy of insertion, you will oblige me by giving it a place in the *Medical Gazette*.

I am, sir,

Your obedient servant,
HANNAM S. THOMPSON, Surgeon.
Dover, Nov. 1837.

Jonas Archer, a mariner, *ætat.* 27, has had gonorrhœa and syphilis; the latter severely, for which he was copiously salivated: has had also ulcers on both his legs, which were open nearly a year and a half, and have only healed up three months.

On August 25th he rowed thirty miles under a very hot sun, and drank a moderate quantity of brandy during the exertion; was well and sober when he reached home in the evening. The following morning, while out walking, he suddenly became giddy, and fell to the ground. In a few minutes he felt partly recovered, and began to walk homewards, but he found that he could not direct his steps. Whatever effort he made he could not prevent himself from reeling from side to side of the road. All this time he was perfectly conscious, and fearing lest passers-by should think him tipsy, he reached home by the most unfrequented paths. He was immediately visited, when there was found a slight hemiplegic affection of the right side. The head was rather hot; both pupils moderately dilated, but perfectly contractile; a little pain over the left temple; pulse a little slower than natural, not labouring nor strong; faculties perfect; articulation quite distinct. Local depletion, brisk cathartics, and an antiphlogistic regimen, were prescribed, and in a few days nearly all the traces of the attack had disappeared; when, on Sept. 15, he was suddenly seized with a violent uncontrollable fit of laughter: this occurred several times in the morning, and in the afternoon he was much worse.

There was now hemiplegia, still slight, of the left side of the body; the powers of the right side being completely restored. His articulation was indistinct, and deglutition difficult;

the pupils were dilated but sensible, and the pulse slow and rather labouring; his sensorium was also confused. He was bled from the arm, freely purged, and a blister was applied to the nape. His hair cut off quite close, and a cold lotion applied. The following day he was much better, *with the exception of his mouth being obstinately closed*. The teeth were so firmly clenched together that they could with the greatest difficulty be separated so as to admit the point of a spoon. The masseters and temporals felt hard and rigid. When a little fluid was poured into the mouth it was swallowed by a sort of convulsive effort, and then only after the lapse of a few moments, and when he was in the recumbent posture. He not only could not articulate in the least, but the larynx had lost the power of even forming a sound. He was perfectly conscious; had no pain; the head cool, pulse slow, small, and feeble; heat of surface natural. Three grains of hydrarg. chlorid. were conveyed into the mouth every three hours. In three days ptialism shewed itself, and from that date he began to recover the power of opening the mouth. He could also make a sort of grunting noise in his throat. The paralytic affection of the left side of the body was likewise diminished.

Nov. 4th.—He can speak, swallow, and protrude the tongue, nearly as well as ever. The faculties of his mind are perfect, and there is no paralytic affection of either side of the body remaining.

Some of the features of this case appear to me to be exceedingly interesting. 1st, the fact, that in the first attack the *right side* of the body was paralyzed, while in the second, (occurring only a few days subsequently) the *left* was similarly disabled. 2d, the complication of trismus with paralysis in the second attack. 3d, the very rapid subsidence of the symptoms immediately ptialism was produced. 4th, the violent and uncontrollable laughter which ushered in the second seizure, and which was far more characteristic of hysteria than a well-marked case of hemiplegia.

It would be a waste of time and space to speculate on these phenomena; still, I would ask, were these hemiplegic attacks caused by sanguineous effusion? If so, was there, or was there not, a distinct effusion on the occasion of each

attack? Is the disappearance of the paralysis of the right side before the supervention of the affection of the left, to be attributed to the removal of the coagulum by absorption, or to an acquired insensibility of the brain to its presence? What is the explanation of the second attack being ushered in by involuntary laughter? Why were the muscles supplied by the eighth and ninth pairs of nerves totally paralyzed, while those influenced by the third branch of the fifth, were in a state of spastic rigidity and contraction.

These questions naturally suggested themselves to me during the progress of the case. I have attempted to frame answers to them, but, however satisfactory to myself, I feel they are not sufficiently well-grounded to justify me in inflicting them on your readers. I shall take care not to lose sight of the case, and in the event of an unfavourable termination I shall take the liberty of forwarding you a description of the morbid changes in the brain.

SOME ACCOUNT OF MESMERISM.

By BARON DU POTET DE SENNEVOY.

[Continued from p. 295.]

AFTER the death of Mesmer, magnetism was forgotten, with all the individuals who possessed a knowledge of it. A conflict of a very different magnitude soon arose in France. Other interests were then to be defended. Every one, amidst the tumult of public affairs, thought of himself, and paid little attention to a truth which sank into insignificance under the pressure of events that riveted the attention of all, and wrought changes in every state.

The disciples of Mesmer, all possessed of wealth and rank, were obliged to expatriate themselves, to save their lives: they bore back the science of magnetism to its cradle. It was studied in Germany and Holland; some of the disciples of Mesmer carried it even as far as America. Thus, during a period of several years, we do not perceive any trace of magnetism in France. Some isolated individuals alone operated in silence, and spread benefits around them, without publishing the results of their practice.

The followers of Puysegur, however,

soon appeared upon the scene, animated by a philanthropy that personal misfortunes had not diminished. They published new works, in which they developed the doctrine, supported by numerous facts. Magnetic somnambulism added to the attractions of magnetism, and physiology and psychology, were enriched by a discovery destined to awaken the admiration of the learned. If the enthusiasm with which it was received was less vivid on this second appearance of magnetism, it was, however, more lasting; less parade was made of this newly discovered truth, and more persons occupied themselves in the privacy of the closet with studying its results. There were, however, some found willing to enter the lists against the incredulous; but having no fixed rule by which to conduct themselves, and not knowing any certain test by which to recognize the real effects from such as might be feigned, they rendered but an imperfect service to the cause. Of this number was the Abbé Faria. He opened a public institution for magnetism, and drew around him many scientific men. Without entering as yet into judgment on the doctrines of magnetism, we should at least render him full justice. He contributed much towards spreading it in France.

Endued with the power to a degree that would be almost incredible, if it were not a known fact that its intensity increases with exercise, he forced several scientific men to acknowledge an agent till then unknown to them. The spirit of the age was positive, and as then, more than ever, it was generally acknowledged that there could be no effect without a cause, the new converts to magnetism esteemed it incumbent on them not to disdain the study of this discovery. They attached themselves, therefore, to this man of wonders, and followed him with increasing ardour; they learnt themselves to magnetise, and soon found that the magnetic effects were produced by a natural cause, depending on our volition; that this faculty was common to all; and that the Abbé Faria did not exercise it by any exclusive charter. More considerable works upon it appeared; the names of their authors, and the reputation they enjoyed, at length permanently fixed upon it the attention of many educated persons.

The major part of the learned, who

remembered that they had been judges in this question, and that they had pronounced its non-existence, shrank from the risk of being obliged to retract; they feared to be convinced, and that they should be accused of having decided too hastily.

Before we proceed further in the history of magnetism, it is requisite to give some account of the means which Mesmer employed to spread his discovery, and to support his doctrine. The effects produced being also those which were submitted to the examination of the first Commissioners, and on which they founded their report, we must, in order to enable the reader to form a just estimate of their importance, carry him back for a moment to that early epoch; and this is the more necessary, inasmuch as the magnetic effects which we are producing at the present day are no longer the same as those exhibited by Mesmer; the means necessary to call them into action are entirely different, and the agents which he considered essential are now neglected.

The following is a description of the processes, and of the apparatus by which Mesmerism was established in France:—

In the centre of the chamber was a kind of tub, several feet in depth, having a cover, with two lids pierced with holes, through which curved and moveable iron rods were passed. The interior was filled with bottles full of water which had been previously magnetised. These bottles were placed in rows, one above the other, so disposed as that the necks of those in one tier were turned towards the centre of the vessel, and their other end towards the circumference; whilst those in the next tier were in the reverse position. The vessel also contained a certain quantity of water, filling up the spaces caused by the disposition of the bottles; but it was not indispensable that every thing should be precisely as above detailed. Sometimes iron filings, ground glass, sulphur, manganese, and many other substances, were put into the water.

The patients were placed round the apparatus, and directed the iron rods to the parts affected. Sometimes the body was encircled by a hoop suspended from above. They occasionally formed what was called the *chain*, by holding each other by the thumb and fore finger. The magnetiser, armed with an iron

rod, which he passed over his patients, appeared to direct at will the course of the magnetic fluid. All this apparatus of water, bottles, and metallic rods, was supposed to be essential to the disengagement of the magnetic agent. Sometimes the operation was accompanied by the notes of a piano or armonica; for it was one of the propositions of Mesmer, that the propagation of magnetism was especially assisted by sound.

These processes formed the basis of the treatment applied to several individuals together. Magnetism could also be exercised in various different ways. The universal fluid being every where, the magnetiser contained a portion of it in himself, which he had the power of communicating and directing by a rod, or by the movement of his extended fingers. In addition to these gestures, performed without coming in contact with the patients, it was customary to touch gently the hypochondria, the epigastric region, or the limbs. To add to the effect of these operations, trees, water, articles of food, or other objects, were also magnetised; for all bodies in nature, according to Mesmer, were susceptible of magnetism.

The patients submitted to this magnetisation experienced various unusual sensations, wandering pains all over the body, but especially in the head and stomach; the augmentation or the suppression of the cutaneous perspiration; palpitations of the heart, and momentary suffocation; sometimes a certain exaltation of the mental faculties, and a vivid sensation of comfort and enjoyment. The nervous system appeared to be more especially affected; the organs of the senses experienced unusual modifications, such as tingling in the ears, dizziness, and sometimes a kind of somnolency of a peculiar character. These effects varying infinitely according to the nature of the disease, and the idiosyncrasy of the invalids, continued increasing in proportion to the duration of the magnetisation, and this series of phenomena terminated also by the most remarkable and most constant of all, viz. convulsions. The convulsive state once excited in a patient, which sometimes did not take place till after several hours, never failed to manifest itself in all the others. This was designated by the term of the *magnetic crisis*. As

this crisis was usually the *dénouement* of the effects produced, it was considered as the object of the magnetic action, and as the means employed by nature to produce the cure.

The convulsions were alarming by their violence and duration. The patients, when seized by them, were immediately carried into a neighbouring apartment, called, on account of its destination, the *Crisis Chamber*, where they gradually came to themselves. One very remarkable circumstance was, that on their recovery they felt only a slight sensation of fatigue, and several even professed to have received a decided relief.

To these physiological results were joined some very extraordinary moral phenomena. Some laughed violently, whilst others, submitted to exactly the same mode of treatment, shed tears. They were frequently drawn towards each other by irresistible impulses of sympathy, and reciprocally testified the warmest affection. But what was most surprising was the prodigious influence possessed by the magnetiser over his patients. An intimation of his will excited or calmed the convulsions; commanded love or hatred; his rod seemed like a magic instrument, to which body and spirit yielded obedience. These astonishing results were also produced, although in a less degree, when he operated on individuals separately.

Such were the effects which the first Commissioners verified, and which they described minutely in their reports.

The Commissioners, however, declared that magnetism did not exist. They were of opinion that all these phenomena might be explained by known causes: they believed that imagination, animal heat, excitement (*Périsisme*) of the skin, and imitation, were the only agents employed by Mesmer; and that the pretended discovery of animal magnetism was a *German rerie*, to be classed with the numerous other reveries which appear and vanish in every age. The report, containing this celebrated judgment, was profusely circulated: but this only stunned public opinion; it did not prevent the progress of magnetism.

The judgment pronounced by the Commissioners was attacked from all quarters. A society existed at Strasbourg which published annals, in which

were inserted facts of magnetisation, contradictory to the explanations of the Academy. Nantes, Bordeaux and Lyons, followed the example of Strasbourg.

The following were the arguments opposed by the magnetisers to the conclusions in the report:—

We admit, said they, that imagination, animal heat, imitation, &c. do produce effects in certain cases, and that these effects are even incontestible.

But we say further, that magnetism can act without the intervention of any one of these agents, and can produce effects which those agents are insufficient to explain.

These are the grounds of our belief. The magnetic action may be exercised in various ways. Some magnetisers touch their patients, hold them by the thumbs, and employ friction; others, on the contrary, content themselves with simply directing their hands in front of the individual whom they are magnetising; finally, others only look at them, and fix their thoughts upon them. All, however, notwithstanding such different modes of operating, succeed in producing the same phenomena.

Now let us examine whether it be the causes specified by the Commissioners which act, or if it be not rather the magnetic agent.

We will begin with *animal heat*. In order, however, that this cause may act, it is necessary to touch the patient; but as we have just remarked, this was not in any degree requisite, as the magnetiser could operate at the distance of several paces.

The case is the same with excitement of the skin. To act on this part, it would still be necessary to rub, or at least touch it; and the proceedings which that mode of treatment required have been laid aside, without the magnetic effects ceasing to appear.

Imitation.—This cause may act in an assembly when several persons are magnetised together; but if in silence and privacy, when the magnetiser is alone with his patient, more striking effects are obtained than in public, then imitation must also be rejected.

We now come to *imagination*, a favourite argument with many. To act by or upon the imagination, the individual to be acted upon should be informed of the effects intended to be produced upon him; he should be made

aware that the operator possesses great power; he should know that he is able to influence him by occult causes, or at least the magnetiser should have command over him either by his attitude or his looks, &c. There is no doubt that by any one of these circumstances it might be possible to disturb his imagination; but if we prove that the effect we produce is so much stronger in proportion as the individual is less aware that we are acting upon him—if we establish by certain and positive facts, that an individual magnetised without his knowledge, and even through a thick partition, is sensible to magnetism—if we see that infants, and those animals of which the organization is the most closely related to our own, are decidedly affected in some way or other when submitted to magnetisation, it must then be admitted that the imagination cannot be considered as the determining cause of these phenomena.

The magnetisers were no otherwise embarrassed than in the selection of the materials by which to prove that the effect produced was independent of the imagination; but their principal argument was this:—When we magnetise adults or children while in a state of natural sleep, we see effects come on almost immediately; and yet they are ignorant of the action exerted upon them. Although we may be placed at the distance of several feet from the magnetised persons, the effect is yet more rapid and more marked than in their waking state, even when they are touched.

No satisfactory answer could be made to these assertions; nevertheless they did reply, but only by negatives. They formally denied the fact; and from that period the magnetisers gained their cause, for they needed only to shew the contested phenomena to those who doubted, in order to insure belief.

It was thus that magnetism took root in France. At the present day very few enlightened men doubt the existence of the magnetic agent; they only dispute its results. But the majority of the scientific know well that the discovery of Mesmer is a truth worthy of the greatest interest, for it is destined to work the greatest changes in the systems of philosophy and medicine.

In the next article, when speaking of somnambulism, we shall shew that it is that singular state which has prevented

magnetism from making a more rapid progress. We shall then explain why the experiments for proving the existence of the lucid state rarely succeed. For the present, confining ourselves to the part of the historian, we only make known the explanations which have been hazarded by some modern magnetisers, to render the magnetic phenomena comprehensible. But the reader ought to be informed that several systems have already existed; that three very distinct schools were formed; that next to that of Mesmer came that of M. Puysegur, and then that of the spiritualists.

The school of Mesmer was founded on a system analogous to that of Epicurus, as explained in the poem of Lucretius. That of the spiritualists, which has many partizans in France, reminds us of the Platonic philosophy. The school of M. Puysegur is founded on observation.

[To be continued.]

SEQUELA OF RHEUMATISM—PHLEBITIS.

To the Editor of the Medical Gazette.

SIR,

THE following case, in which the veins of the right leg became secondarily inflamed from rheumatism, was admitted into St. George's Hospital a few years ago; and as several lectures are now in the course of publication on "Rheumatism and its effects," in the MEDICAL GAZETTE, I thought it might be sufficiently interesting to occupy a small space in the same journal.

Your obedient servant,

C. J. B. ALDIS, M.D. Cantab.

13, Old Burlington Street,
Nov. 10th, 1837.

George Emerly, æt. 23, painter, admitted November 9th, 1831, under Dr. Chambers. Pulse 108; skin cold; tongue red, with a brown fur, and a red streak along the mesial line; bowels open from medicine; urine free at present.

Complains of pain in the left hip and thigh; pains also in the shoulder and in the right leg above the ankle, shifting from one spot to another.

Attacked twelve weeks ago with cough and expectoration, and about eight weeks

since with the pains in his legs. Has been confined to his bed six weeks. Has been twice bled, blistered on the chest, and had leeches applied.

R. Pil. Hydrarg. gr. iv. omni nocte.
Rhei Pulv. ʒj.; Aq. Piment. ʒiiss.
cras mane.
Aq. Dist. ʒiiss.; Acid. Nit. ℥iv.;
Sacch. Albi, ʒss. ter die.
Diæta lactea.

11th.—Pulse and skin natural; tongue much cleaner; bowels open.

Rep. Haust. omni mane.
Diæta è pisce.

13th. *Vespere*.—Was attacked with symptoms of phlebitis in the right leg, and pain in the lower part of the abdomen.

R. Mist. Ætheris C. ʒj.; Liq. Opii Sedat. ℥xx. statim.—Fotus abdomini.—
Hirud. xij. femori, postea cataplasma Lini.—Fetus Papaveris cruri.—Hydrarg. Submur. gr. ij.; Opii gr. ss. 4tis horis.—Rep. Haust. Rhei mane.

14th.—Was attacked yesterday evening with pain in the lower part of the abdomen, which spread to the thigh and leg. At present the leg and thigh are swelled and tense, the former slightly œdematous, and the synovial membrane of the knee-joint is distended with fluid; abdomen still tense and tender. Relieved by the leeches: pulse 120, hard and jerking; tongue white, brownish along the centre.

V. S. ad ʒx.—Hirud. xij. femori.—
Catap. Lini et Fotus ut antea.—Rep.
Calom. et. Opium.
15th.—Olei Ricini, ʒiij. statim.—Rep.
V. S. ad ʒx.—Enema Oleosum.—
Haust. Salin. Efferv. 4tis.

16th.—Pulse much softer, still frequent; tongue furred; bowels open, with ochrey motions, very offensive; abdomen much less swelled and tense; still some tenderness in the right ilium; the leg still much swelled, with a tense œdema occupying the whole thigh and leg, with much tenderness. Blood drawn yesterday much inflamed: frequent hiccup.

Hirud. xx. femori, postea Catap. Lini amplum; applicetur abdomini 4tis horis. Catap. Sinap. per horæ ½.—
Haust. Ætheris C. urgente singultu.—Omit. Haust. Efferv.—Soda water.
18th.—Rep. Hirud. xij. Enema Oleosum.

From this time the symptoms gradually subsided, and the patient was cured in December.

MEDICAL GAZETTE.

Saturday, November 25, 1837.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri: potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

ON THE REMUNERATION OF
MEDICAL MEN.

OUR motto bespeaks us the defenders of the *dignity* of our profession, but we may, we hope, lay claim to some merit for having also maintained its more tangible interests. We have lately called the attention of our readers to some instances in which it has seemed to us that the services of medical men are most inadequately remunerated; and certainly there cannot be a more striking anomaly than the degrees of esteem (as evidenced by pecuniary reward), in which medical services are held by the same individuals, when acting for themselves, and when acting for the public or for smaller communities.

The governor of a charitable institution, for example, willingly tenders his fee for the cure or relief of a malady from which he himself suffers; but, acting in concert with others, he deems that a formal return of thanks is sufficient to repay the labours of the same physician or surgeon in the relief of the objects of his compassion. The director of an insurance-office, again, will not hesitate to pay for attendance on his own, it may be, trivial disorder; but he thinks that the time and opinions of the same person may be fairly given for the benefit of the company to which he belongs. We never heard of a coroner who expected to receive prescriptious gratis, but we have of many who refused to repay their medical attendant for all the trouble and responsibility of obtaining and giving evidence; and we should regard it as a most remarkable

occurrence, if a commissioner of the poor-laws, or an overseer, expected to be cured by contract, or preferred to have his medicines on the lowest possible tender, rather than draw his purse-strings for a sufficient repayment of the services rendered to him as a private individual.

The claims of medical men seem to be estimated in a very similar manner by the whole public. The amount of fortune which some have acquired in private practice are sufficient to testify how generously all are ready to reward benefits bestowed on themselves. Look, for instance, at the incomes of some of the more eminent: Dr. Meade earning and spending more than any contemporary, of whatever trade or profession; and Dr. Baillie receiving 11,000*l.* in eight months. Or to come to modern times, see the station which the leading men of the profession maintain in society—their household, and their equipages. Is it not strange that these very men should be expected to devote the hours in which they might increase their incomes almost indefinitely, to gratuitous attendance in the public service? Yet the very men whose incomes at the present time testify the value which private individuals set on their services, are gratuitously giving up some hours, nearly every day, in attendance on objects of charity, or in other works tending to the public good, and this without receiving more than constrained thanks from those in whose immediate service they are engaged, or having the credit among the public of being in the slightest degree more liberal than the members of other professions, who only work for and according to their pay.

We look in vain for analogous instances in other callings of gratuitous services, in works either of charity or of public good. In the law, for example,

those cases are the exceptions to an extensive general rule, in which its members are not paid for the occupation of their time and talents in the causes of charitable institutions, at the same rate as for other business; and so, too, whenever they are concerned in works of humanity, or of science, or generally in such as contribute to the good of society. Were it to be gravely proposed, that the defence of all benevolent institutions against actions or injuries—that the conveyances of titles to all their estates, and all their legal business, whether requiring the assistance of a barrister or attorney, should be gratuitously performed—it is easy to conceive the ridicule with which the proposition would be received; and yet the law, like medicine, is called a *liberal* profession, and its members do not fail to claim their title to this honourable appellation with as much earnestness and vigour as they defend their pecuniary claims. Some, indeed, find it difficult to establish both these claims, but consider themselves well recompensed for their losses in one, by being able to laugh as they win in the other.

If we look through the items of expenditure of a charitable institution, the only name that is ever missed is that of a medical attendant. Attorneys, surveyors, builders, government officers, parish authorities,—all have put in their claims, and been satisfied; and the one who, in many cases, as in infirmaries, hospitals, &c. has rendered the most important services, alone remains unpaid. Even in the largest institutions the only medical man (as a general rule) who receives a salary, is the resident apothecary, who is prevented from practising in private, and whose time is entirely devoted to the affairs of the institution. We know an hospital, where a gentleman employed as clerk to

the governors, and to conduct their legal transactions, receives 300*l.* a year, has a handsome house, rent free, and is, besides, paid for all law business as between attorney and client; while the medical officers to the same establishment receive a merely nominal salary. We do not mean to say that, in this instance, the gentleman to whom we allude is too well paid; his services doubtless fully merit their remuneration; but we place the case here for contrast's sake, and may add, that while he is not professionally known beyond the walls of the institution, the medical officers are all men of eminence, and receiving large incomes in their private practice.

In short, look where we may, we find no profession or trade wherein public services are given gratuitously, except our own; and it is not a little annoying to find that they are received as if those to whom they are rendered were legally entitled to them, and that the only anxiety shewn is to obtain more at the same cheap rate. But this we sincerely hope the profession will in a body resist. Let all that is required in adding to the efficiency of charitable institutions be given, and payment never once asked for; and let it be given conscientiously and liberally: a medical man can enjoy no greater satisfaction than he will receive from the assurance that he has employed his time and talents as diligently for the relief of those who were dependent on his charity, as of those from whom he received the largest donations, and we should be sorry in this respect to see the present system (except in a very few cases) at all departed from. At the same time, it must be said that the members of our profession are entitled to more thanks and credit from the public than they ever receive; and seeing that, in these cases, those whom they serve are so little grateful, let them in all others refuse to render their as-

sistance without adequate pecuniary remuneration being in some way insured to them. It was long since well observed that every thing is valued according to the sum it cost to be obtained, and we have no doubt that medical men will find the services for which they now receive neither fees nor thanks, repaid with thanks and money too, when the latter only is demanded.

But some one will say, these gratuitous services are not forced upon medical men, and therefore why do they undertake them? Nay more, why do they anxiously contend to obtain the situations in which they may render them? Now we are not disposed to deny that in many cases where there is no direct payment made for services to charitable institutions, an indirect remuneration is obtained; but we contend that this is very uncertain, and the hope of it often altogether fallacious. In the larger hospitals, for instance, to which schools are attached, the fees of pupils afford a considerable income to some of the medical officers, but these are subject to great fluctuations, according to the management of the institution, the reputation of the lecturers, &c. We need not go out of the metropolis to find an instance where, from a failure in one of these essential circumstances, the income of the officers derived from this source is not much more than nominal, and this in no degree the consequence of their own fault, or their own want of public reputation. The prospect of obtaining a large connexion among the governors of the various institutions, seems to attract many to all the troubles, and even degrading annoyances, of contests for these situations; but, as a general rule, there is no more illusive hope: we know many who have for years been medical officers of hospitals and dispensaries of various extent, and who allow that they cannot remember to

have received a single guinea which they could trace to their connexion with the governors; who, indeed, seemed to think them amply repaid by the votes, which enabled them to give their gratuitous services.

But these are only a part of the calls which are made on the time and services of medical men. In coroners' inquests, for instance, the remuneration is generally quite inadequate, obtained with trouble and difficulty, and at the expense of much anxiety and responsibility, and always given grudgingly; while the annoyance is heightened by seeing the members of the sister profession regularly, and without difficulty or remark, receiving their accustomed liberal, but not more fairly-earned, fees.

In all matters of public hygiene, &c. medical men, in common with other men of science, are generally expected to give their opinions gratuitously; while others, and even those who are to be profited by the results of the inquiry, are receiving adequate payment. In the instance to which we alluded last week, insurance-offices which refuse to pay a medical man for his opinion on the probable life of one who is about to be a source of profit to them, do not hesitate to pay a guinea to each director every week that he will come, and have a few hours' conversation with some friends, on his own and their business; and this, too, while the directors are generally men of leisure, retired from business, with little else to engage their attention; whereas the medical man has to abstract his time from other engagements in which pecuniary remuneration would be certain.

Perhaps the most flagrant instance in which medical attendance for public good is insufficiently repaid, is in the case of the poor; but on this we have written already too often to need much further remark. It is a striking ex-

ample of how little respect is paid to those who demand little. Practitioners not only admitted the system of contracts, and allowed their time and (where it existed) talent, to be sold like so much bread, or cloth, at the lowest possible price, but they entered into it with as much alacrity as if trade were their element; and even surpassed, in many instances, all the tradesmen, in their anxiety to be permitted to degrade themselves and their profession. They have been taken at their own price, and having once shown their willingness to move downwards in the scale of respectability, the efforts of all they are concerned with will henceforward be directed to push them still lower. But it is now fully time for them to stop. In every charitable cause, we hope the profession will be unanimous in giving their services, and that every individual will conscientiously exert himself to relieve the suffering poor, with as much attention and assiduity as he would in the case of his most munificent patient: nothing can be lost by this. But in scarcely any other instance of public duty, should they permit themselves to be unpaid. We recommend them, in short, to act in all these cases as the members of the legal profession do. We believe, that if they will follow this advice, they will increase in public esteem, in exactly the same proportion as their incomes from these hitherto unprofitable sources improve.

PATHOLOGICAL CHAIR.

WHEN we last alluded to this subject, we stated that Dr. Thomson, who had come to London for his health, had been obliged to return to Edinburgh, in consequence of the Town Council having refused to allow his deputy, Dr. Simpson, to lecture. Since that time the opinion of the Dean of Faculty has been received, and it proves to be in favour of the Professor's right to ap-

point another to officiate for him, in the event of his being himself incapacitated. It is obvious, that under the circumstances this point of law ought to have been ascertained at an earlier period, as Dr. Thomson has been put to great and unnecessary inconvenience. It is, however, to the general question of the expediency or inexpediency of having such a chair at all, that we wish to direct attention, because we know that a strong effort is being made in the new University to establish a separate course of Pathology as a portion of the curriculum; and a strong belief prevails that this results from a desire to serve one particular party, just as happened when the chair was established in Edinburgh. Now, acknowledging as we do that the gentleman in question is a most accomplished morbid anatomist, we must still protest against this as an unnecessary tax upon medical students, and an unwarrantable infringement on the department of other teachers.

In an Edinburgh paper before us, we find it stated that the question of instituting separate lectures on pathology was brought under the special notice of the Royal Commissioners, appointed some years ago to visit the Scottish Universities; and that they, after mature investigation, decided against it. "The subject," the learned Dean says, "was most anxiously considered by the Royal Commissioners; and *after examining all the medical men of science, and receiving opinions from all quarters*, they were unanimously of opinion that a separate class of pathology ought not to be instituted." We trust the Council of the University of London will give due weight to the opinion above expressed, as well as to the strong feeling which exists upon this subject, and avoid beginning their career with what, if carried into effect, will be generally regarded as a job.

CLINICAL LECTURE

ON

FRACTURE OF THE SKULL,

WITH DEPRESSION AND INJURY OF THE
DURA MATER AND THE BRAIN;

AND ON

CANCER OF THE LIPS.

Delivered at St. Bartholomew's Hospital,

BY WM. LAWRENCE, Esq. F.R.S. &c.

THE case to which I now direct your attention is a severe injury of the head—a comminuted fracture of the cranium, with bone beaten in on the brain, and portions of the latter forced out through the wound. An important practical question arises in the treatment of such injuries at two periods of their progress, namely, whether the injured bone should be exposed and elevated, or removed, at the time of the accident; and whether, if this has not been done, the measure ought to be resorted to at a subsequent period, if serious symptoms, such as convulsions and paralysis, should supervene.

Thomas Bennett, 13 years of age, a nobleman's groom, was in attendance on his master, in the neighbourhood of the House of Lords, on the 6th of April. He was mounted on a high-bred horse, which took fright and ran away with him, the lad not being strong enough to hold him in. The animal went at full gallop along Parliament-street and Whitehall, until it was stopped by a timber-waggon, which was turning into Scotland-yard: against this it came with full force, receiving so severe an injury, that it died within half an hour. The boy was thrown violently forwards, and his head came in contact with a piece of the timber. He was picked up and conveyed into a neighbouring house, where I saw him almost immediately. He was insensible from the shock of the injury, but could move his limbs: he was breathing naturally, and his pulse was not materially affected: he had thrown up the contents of his stomach. The upper and right part of the head was covered by a large mass of clotted blood, which I removed with my hand, and found, on turning it over, that it contained portions of brain, which might have been about sufficient to fill a dessert spoon. This had escaped through a wound of the scalp, about one-third of an inch in length, just over the coronal suture. There was a fracture of the right parietal bone, which could be traced under the integuments from the back of the bone to the situation of the wound, at

which there was a considerable and irregular depression. He was conveyed in a coach to the hospital; and a further escape of cerebral substance, to a small amount, was found to have taken place when he arrived. At the end of two hours he manifested sensibility on being pinched; he moved his limbs readily; the circulation, respiration, temperature, and colour of the skin, were natural.

As the bone was here evidently and considerably depressed, and as it was also probably driven in upon the brain, it would, I believe, have accorded with principles of treatment generally admitted, to have performed an operation for the purpose of elevating and removing depressed and detached portions of bone. The considerations which determined me not to do this were, the favourable state of the patient generally, and in particular the absence of all symptoms indicating compression of the brain; the specimens, in pathological collections, of very extensive injuries of the skull repaired by a natural process; the smallness of the external wound, which brought this case nearly into the state of simple fracture; the extensive incision of the integuments, and exposure of the bone, dura mater, and brain, which an operation would have involved; and the almost invariably fatal termination of such proceedings, within my own experience in hospital practice. In the latter respect, the chances are less unfavourable in a young than in an older subject; on the other hand, the powers of natural restoration are more vigorous in the former than in the latter. On the whole, I consider the dangers attendant on such an injury as that which befel this poor lad, to be much less than those belonging to the operation, which would have been required in this case.

A strictly antiphlogistic treatment was adopted, comprising perfect quiet, opening medicines and clysters, and tea diet. The head was shaved, and kept cool by the repeated application of cold cloths; and the wound was kept open, that blood or effused liquids might escape readily. In thirty six hours after the accident, the external senses and the mental powers were completely recovered, and speech was restored. When questioned, he complained of pain in the head, which continued more or less for about ten days, and was the principal symptom referrible to the accident. On the 9th, the neighbourhood of the wound was red, hot, and painful, and there was restlessness. The application of six leeches removed these symptoms.

The entirely favourable progress of the case seemed to justify the course which had been adopted; but new and alarming

symptoms appeared on the 11th. There was some increase of temperature in the head, and general feverishness. Convulsions came on in the face and right limbs, while the left arm and leg were completely paralysed. The question of operation was again considered. I did not refer these symptoms to pressure of the displaced bone, believing that if any effect had been produced by that cause, it would have followed the accident immediately, and I thought the present symptoms must be ascribed to the inflammation of the brain, which might be expected after such an injury. The external wound was opened and probed, and gave issue to some bloody matter. Four leeches were applied in the neighbourhood, and were followed by bread-and-water poultices. Four grains of the hydrargyrum cum cretâ were given every four hours. A blister was applied to the nape, and the vesicated surface, after removal of the cuticle, was dressed with strong mercurial ointment. The mischief was speedily and effectually arrested by these means. The convulsions which had come on in paroxysms, did not return after the bleeding. The left arm and leg remained totally powerless for forty-eight hours, and then recovered slowly, but completely. The mercury quickly affected the mouth, and lowered the pulse, which became slow and feeble, with considerable sense of weakness. It was therefore necessary to give it up entirely at the end of a week, and to allow some improvement of diet. The strength and health soon returned, and the patient became quite well, except that discharge of matter continued from the original wound, and from another small opening, which had been made a little lower down. The integuments had remained detached from the bone to a considerable extent from the time of the injury, and matter had accumulated under the loosened portion of scalp; a counter-opening had been made to allow a dependent discharge. Matter can still (June 3) be pressed out from both apertures, and a rough portion of bone can be felt with the probe introduced at the original wound. In all other respects this patient, who has for some time left his bed, is in perfect health: there is not a trace of imperfection in the senses, mental faculties, or the power of moving the limbs which had been paralysed.

T. Bennett remained some time longer in the hospital, in the expectation that a portion of bone would come away, and because a quiet mode of living, with strict attention to diet, was thought necessary until the part had become sound. No exfoliation, however, took place, and he left the hospital with the opening in the inte-

guments still occasionally discharging. He came occasionally, that we might watch the progress of the case. In about a month the wounds had firmly cicatrised, and no evidence of the injury remained, except a considerable indentation of the skull where the bone had been broken.

Cancerous Affections of the Lips.

I have the opportunity of showing you two specimens of cancerous disease of the lips, which I have removed in the last two days. One was taken from the lower lip of a patient about fifty, in whom the disease had existed five or six years, without pain or material inconvenience; having, indeed, attained only a trifling magnitude. It was seated at the boundary between the mucous membrane and the red edge of the lip, occupying an equal portion of both structures, and consisted of a small indolent induration, causing a slight swelling of circular outline, less in circumference than a shilling, with an ulceration in the centre, covered by a brown incrustation. It had commenced as an indurated tubercle, and had not been long ulcerated. This gentleman had never smoked. There was no affection of the absorbent glands. Ineffectual attempts had been made to destroy the disease by escharotics. I sliced off the morbid production by passing a double-edged knife under its basis. The diseased part presents a small mass of firm scirrhus induration; while the ulcerated portion is a broken surface, like that of some warts.

The other specimen exemplifies what is less frequent—namely, cancer of the upper lip. The patient from whom I removed it is a healthy person, near seventy, living in the country, and following the occupation of a farmer. Two years ago the disease began, as a wart on the integument of the upper lip, at least half an inch above the red portion. The hardened part ulcerated, and the complaint slowly spread downwards. There has been little or no pain, and the absorbent glands are unaffected. You see in this specimen a cancerous ulceration of the integument, about three-quarters of an inch in length, and half an inch wide. The edge is knotted, irregular, and hard, and the surface of the sore is uneven: it is bounded below by the mucous membrane of the mouth, which is sound. It produced a sparing discharge, which formed a hard adherent incrustation. I removed this disease by a semi-circular incision, in the manner recommended by the late Baron Dupuytren, which I have found to answer the purpose perfectly well in several instances of similar operations. A section of this disease shows that it is a specimen of genuine cutaneous cancer; the cutis having been

converted into a stratum of compact scirrhous structure, about a line in thickness, and the surface of the part thus altered having become ulcerated. The surrounding adipose, muscular, and mucous structures were quite healthy.

These examples show us that the disease in the lip may begin either in the common integument or in the red edge of the mucous membrane; that its characters are the same in both instances—namely, tubercular induration, proceeding to ulceration; indolent nature, slow progress, and absence of affection of the absorbent system. Disease exactly similar in nature and in progress is seen not unfrequently in the integuments of the cheek, nose, and lower eye-lid. The important difference between these several cases and cancerous affection of the mammary gland is, that the absorbents are not affected in the former, and thus that we may remove them with the knife, without any fear of those unpleasant subsequent occurrences which so frequently frustrate, in the end, our attempts at curing scirrhous disease in the breast by operation. I have removed portions of cancerous integument from various parts of the face, with complete success, in numerous instances, when the disease has been so situated as to allow the complete extirpation of the morbid structure, and the absorbent glands have been unaffected.

The latter ultimately become diseased in some cases. There are also malignant diseases of the lip, commencing in the interior, consisting of the successive occurrence of induration and ulceration, and affecting the absorbents at an earlier period. The present remarks are applied to those instances only in which the affection begins with tubercular induration of the external skin, the red edge, or the mucous membrane.

The superficial nature of the disease in these cases might induce us to attempt their destruction by powerful escharotics, such particularly as the chloride of zinc. I think the use of the knife preferable, as being more definite and certain: we remove all that ought to be taken away, and we do no more. It is, at the same time, far less painful. Some time ago I saw a lady with an affection of this character on the left temple; it was about the size of a sixpence; the mass of induration being inconsiderable, and the ulceration not deep. It was, however, very painful. Her sister had died of cancer in the breast, the disease having returned after an operation, and this had given her a great aversion to the knife. I applied the chloride of zinc, which certainly removed, both in surface and depth, fully as much as would have been taken away by the knife.

The application was followed by the most severe pain, which lasted for several days and nights. The separation of the slough was followed by healthy granulation, and an apparently sound cicatrization. Within a month, however, an indurated tubercle formed in the cicatrix, and was very painful. The patient now readily consented to the use of the knife. The part was freely removed, and there has been no recurrence to the present time, a period of more than twelve months.

Irritating and escharotic applications are not unfrequently tried to those diseases, almost invariably with the effect of inducing pain and increased activity in a complaint previously indolent and nearly stationary. I recommend to you, therefore, in the management of these cases, a choice between two courses; that of leaving things alone, or complete extirpation by the knife.

A few days ago I operated on an infant in the hospital for hare-lip. The fissure was confined to the lip; the child had thus been able to suck, and was still at the breast. The eligible time for this operation is before the first dentition, about the fourth or sixth month. The sides of the fissure were brought together with a silver pin, and the twisted suture at the red edge of the lip, and a simple suture at the upper part. I allowed the child to continue at the breast, having found, by experience, that the act of sucking does not interfere with the process of union, while it is much better for the health of the patient that it should continue to receive the wholesome nourishment provided for it by nature.

A FASTING WOMAN.

It was cried about the streets of Paris, that a woman of clear complexion and plump habit, suckling a large child six months old, had eaten nothing for a year and eight months. As she did not eat, she necessarily must have had no evacuations, and this was also asserted; so that the miracle was complete.

It was added that she had the power of living on water alone, without making the slightest effort, or even moving at all.

She was admitted into the Hôtel-Dieu on the 30th September, and is now in the St. Monica ward, No. 60, under the care of M. Magendie. Her name is Maria Rosa Felicity Hardy, and her age is thirty-one; she is a char-woman, and born at Catigny, in the department of the Aisne. She is neither fat nor lean, but, if any thing, rather inclining to the latter, and of a sanguine temperament.

For the first few days it could not be perceived that she took any nourishment.

At any rate she touched nothing that was placed near her bed, either solid or fluid; nor was any evacuation discovered.

She was then in the St. Benjamin ward, under the care of M. Caillard, who did not believe in these wonders, and thought that he should sooner or later find out that she was a trickster.

M. Caillard not being able to put this woman under lock and key in his wards, sent her into those of M. Magendie, who had a small room at his disposal quite fit for experiments of this kind. The woman was shut up with food, of which the quantity was exactly measured. She seems to have fasted for eight days, unless indeed she received nourishment secretly, and without the knowledge of the physician; but on the ninth day she ate. Faeces were found very well concealed in a mattress, which she had sewed up again. After this there was no interest in continuing the experiment; she was removed from the room, and had a bed in the ward.—*Gazette des Hôpitaux.*

PHYSICAL SOCIETY, GUY'S HOSPITAL.

Fourth Meeting, Nov. 18, 1837.

EDWARD COCK, ESQ. IN THE CHAIR.

On Normal and Abnormal Dentition in Adults.

MR. EDEN read a paper on the above subject. The first part of the paper was devoted to the description of normal dentition: the author then proceeded to the consideration of some of the most usual deformities, their causes, effects, and treatment. In alluding to the second dentition, and growth of the jaws, the author strongly insisted on the consentaneousness of these processes; he considered, however, that the roots of the temporary teeth acted as wedges to separate the permanent pulps from each other. Abnormal dentition was believed by the author to be less frequent in the country than in large towns: he was led to such opinion from a conviction that the disadvantages, arising from the artificial life, &c. adopted in populous districts, would tend to injure the general health, and thus act as a cause in producing irregularity of the teeth. Family peculiarities were as powerfully impressed on the teeth as on the other organs of the body. The author divided the irregularities of the teeth into the irregularities of growth and irregularities of disposition. With regard to the former, he referred to the papers by Dr. Ashburner, published in the *MEDICAL GAZETTE*. The most common irregularities of disposition were believed by

the author to be those in which the canines and superior incisors were principally implicated; the canine pulps being abnormally situated, or the jaw not enlarging in proportion to their growth. The treatment of abnormal dentition was entered into at some length by the author: he particularly condemned interference with the processes adopted by nature, except in cases of most absolute necessity. He concluded by saying, that it was quite impossible to lay down any general rule of guidance in the treatment of irregularities of the teeth.

A question having arisen as to the number of germs of teeth in the earliest period of foetal life, Dr. Ashburner being called upon, said, that, according to Serres, fifty-two germs of teeth existed in the foetus. Rousscan, in his *Système Dentaire*, stated that Geoffroy St. Hilaire declared the germs of all the teeth could be discovered in all animals at the earliest period of their uterine existence. These were considered by him as so many foetal organs, for which certain vessels were predestined; hence a regulation of the flow of blood through the head was procured. Dr. A. alluded to the difficulty of forming a correct standard of health. He agreed with Mr. E. as to the consentaneous growth of the teeth and jaws, but differed with him in his explanation of the progress of this development; for he did not believe that any local source of irritation, such as wedge-like pressure, was necessary to produce a perfectly healthy result; the truly healthy operations of the human body depended more upon the vitality, nervous energy, power of growth, &c. of the individual, than upon any local action: when local irritation existed, then abnormal dentition was the result.

MR. COOPER objected to Dr. Ashburner's principle of examining the whole system to account for local growths. He thought it more correct to make local examinations to explain local operations. Mr. C. referred to a preparation made by Mr. John Hunter, in the College Museum, of a foetus three or four months old, where the germs of the deciduous teeth alone existed, and occupied the whole of the jaw; there was no trace of the germs of any of the permanent teeth. These facts were further detailed in Mr. Hunter's work on the teeth; but Mr. C. said he himself had not pursued this branch of anatomy minutely.

DR. ASHBURNER called the attention of the Society to a fact mentioned by Serres, which it would be very interesting to confirm. Serres stated that there were two sets of vessels for the two dentitions: these were traceable in the lower animals. Dr. A. had seen this arrangement in four

specimens of the dry jaw, but would not undertake to say that this was the general rule.

MR. GORHAM took a more extended view of the subject than had been hitherto done. He had 300 observations to shew that the growth of the parietal bones kept pace with the progress of dentition; thus, when the anterior fontanelle was large and open, the teeth were cut late, and when the parietal bones were nearly united, the early dentition could be confidently prognosticated. Mr. Gorham endeavoured to explain this by arterial connexion.

MR. GREENWOOD thought Mr. Gorham had erred in his explanation. In weak children the fontanelles were always large, and the teeth cut late: both circumstances attributable to a general and not to a local cause.

MR. ROBERTS was of opinion that the health of the individual very much affected dentition. He mentioned the case of a child becoming hydrocephalic at the period of weaning, whose milk teeth appeared without enamel. The permanent set had only a thin coating of that structure.

DR. ASHBURNER entered at some length into a description of the process which nature adopts in absorbing the roots of the milk teeth: he compared it to the action observed in necrosis, where a sequestrum of bone becomes absorbed. He said he believed Mr. Bell thought that the growth of the jaw was partly produced by the wedging of the teeth; but he could not agree with that gentleman.

MR. COOPER, in alluding to the pathology of dentition, asked Dr. Ashburner whether he might not possibly have mistaken cause for effect. Why was it more likely that the bad state of health observed by him should be caused by the teeth, than that the irregularity of the teeth should be caused by a general affection of the system?

DR. ASHBURNER said he could not agree with Mr. Cooper, and quoted cases in support of his position. He decidedly had remarked (in many cases) the existence of general constitutional disturbance during the second dentition.

DR. ADDISON, in reply to Dr. Ashburner, declared that he had never observed general mischiefs to exist during the second dentition. He thought one source of fallacy might be detected in the Dr.'s views, viz. that during the period of second dentition the patient was at the age when scarlatina, variola, rubeola, &c. are known to occur. Dr. A. quite agreed with Mr. Greenwood, regarding Mr. Gorham's observations; it had been long known that those children who had large bregmata,

were weakly, and therefore cut their teeth late.

MR. COOPER proposed, and Dr. Addison seconded, a vote of thanks to Mr. Eden, for his valuable communication, which being unanimously carried, the meeting adjourned.

At the next meeting, December 2d, Dr. Guy in the chair, Mr. Iliff will read a paper on the difficulty of distinguishing the commencement of malignant diseases in the abdomen, illustrated by a case.

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Mr. SCOTT, *Surgeon*.

Mr. HAMILTON, *Assistant-Surgeon*.

Nov.	Sex.	Age.	Case.
7.	M.	14	Fractured tibia and fibula.
	M.	14	Burn from gunpowder.
	M.	50	Wounded head.
	F.	27	Sprained ankle.
8.	M.	42	Wounded head.
	M.	14	Wounded head.
	M.	36	Fractured tibia and fibula.
9.	M.	40	Fractured ribs.
	M.	20	Injured abdomen.
	M.	21	Contusions.
	F.	30	Laceration of the leg.
	M.	4	Retention of urine (<i>a.</i>)
10.	M.	46	Cut throat (attempted suicide.)
11.	M.	11	Burn from gunpowder.
	M.	38	Fractured tibia and fibula.
	M.	56	Cut head.
12.	M.	69	Hernia (reduced.)
	M.	29	Cut throat (attempted suicide.)
	M.	3	Scald (dead.)
	M.	2½	Scald.
13.	M.	44	Injured shoulder.
	M.	69	Injured side.
	M.	42	Fractured fibula.
	M.	47	Sprained ankle.
	F.	8	Burn (dead.)
	F.	67	Burn in the head (dead.)
	F.	28	Wounded leg.
	F.	72	Fractured femur.

In-patients 28

Out-patients 35

Total 63

(*a.*) This boy was admitted with incomplete retention of urine; his mother stating that only a small quantity had occasionally dribbled from him for the last four days; she attributes this to a kick the boy received from a cow. On introducing a small catheter it was distinctly felt to grate over a small calculus, near the mem-

braneous portion of the urethra. The water was drawn off three times a day, and on the 16th the urethra was cut down upon, and two very small calculi removed. The case is doing well.

CHAIR OF ANATOMY—UNIVERSITY OF DUBLIN.

(From a Correspondent.)

ON Monday the 6th instant, Dr. Harrison, Professor of Anatomy and Surgery in the University of Dublin, commenced the course of lectures on Comparative Anatomy, to which the public have free access; the professors being remunerated for these, and the public lectures on chemistry, at the expense of the University. The theatre was crowded to suffocation.

Previously to commencing his course, the Professor, after a well-deserved compliment to his predecessor, Dr. Macartney, made some forcible remarks on the importance of both general and professional education, as preliminary to medical graduation. After describing the advantages connected with the Irish School of Physic—the anatomical opportunities—the University anatomical and chemical establishments—the botanical garden—and the splendid hospital connected with the school, and founded by Sir Patrick Dun—the Professor observed that the University of Dublin was the only one in the United Kingdom where medical education was *duly* combined with study in arts; it being in the power of those candidates who chose to unite them, to obtain a full and recognised degree in arts, and also that of Bachelor in Medicine, at the commencement in immediate succession, or in little more than four years from entering the University.

The public courses of anatomy and chemistry have continued to attract a crowded auditory.

DR. A. T. THOMSON'S CONSPECTUS OF THE PHARMACOPŒIAS.

To the Editor of the Medical Gazette.

SIR,

HAVING been induced, by an advertisement on the cover of your journal, to purchase Dr. A. T. Thomson's tenth edition of his *Conspectus of the Pharmacopœias*, professing to contain all the *alterations and additions* of the last London Pharmacopœia, I was disappointed in finding, in such a useful little manual for the table of the practitioner, so many omissions of important articles in daily use in modern practice, and which have a place in the

London Pharmacopœia. In my cursory survey of the work, I find *Ergota* and *Strychnia* altogether omitted, and *Creosote* and *Veratria* only mentioned among the poisons; the former as an *acid poison*, and the latter as an *acro-narcotic poison*, without the least reference or direction about them in a medicinal view. *Morphia* and its preparations are placed among the *useful remedies* employed in the *United States and France*, having, by inference, no place in the London Pharmacopœia. *Carbo Animalis*, *Porcira*, *Potassa*, *Bromidum*, and *Potassa Ferro Cyanidum*, all articles in the London Pharmacopœia, are wholly omitted. The book is also dedicated to the Junior Members of the Profession, under the date of March, 1837. To me, an elder member of the profession, such omissions matter little; but when put into the hands of those for whom it is designed, and especially into those of the student on his way to the Hall or the College, these *corrigenda* are culpable, and the advertisement is fallacious.—I am, yours, &c.

MEDICUS.

Nov. 8th, 1837.

[The above is from the pen of an eminent provincial physician, who sends his name. We have farther satisfied ourselves, by a reference to the "*Conspectus*," that the omissions to which he alludes actually exist.—ED. GAZ.]

UNIVERSITY COLLEGE HOSPITAL.

FATAL BAYONET WOUND.

To the Editor of the Medical Gazette.

SIR,

A JOURNAL, notorious for its mendacity, having made some very false statements respecting the case of a man who lately died in University College Hospital, from the effects of a bayonet wound, I judged it necessary to advert to this subject in the lecture on Punctured Wounds, delivered by me, at University College, last night.

As several of my friends think that the observations which I there made ought to be rendered still more public, inasmuch as they afford a complete exposure of the wilful misrepresentations resorted to by the Editor of that publication, as well as of his disgraceful ignorance of practical surgery, I have decided to comply with their advice. The remarks were completely extemporaneous, and I have no copy of them at present; but I will prepare one, and transmit it to you in the course of two or three days.—I am, sir,

Your obedient servant,

S. COOPER.

Woburn Place, Russell Square,

DR. JAMES FORBES.

DIED on the 7th instant, in Maddox-street, in his 59th year, Dr. James Forbes, Inspector-General of Army Hospitals. On his return last year from Ceylon, where he had served with great credit as Deputy Inspector-General, he was promoted to the important appointment of Inspector General of the Hospitals in the King's Army on the peninsula of India. Dr. Forbes was a man of high talent, a distinguished medical officer of the army, and enjoyed in a singular degree the regard and respect of all the officers, medical and military, with whom he had served in almost every quarter of the world.

LECTURES
ON THE
PHYSIOLOGY AND DISEASES OF
THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

LECTURE VIII.

Physical Examination of the Chest (concluded) — Methods of Auscultation — Directions for Percussion — Pleximeter — Immediate Auscultation — Advantages of Mediate Auscultation — The Stethoscope, its Principles and Construction — Different kinds of Stethoscope — Directions for using the Stethoscope.

WE are to be occupied to-day, gentlemen, in considering the *methods* of physical examination, or the means which we use to obtain a cognizance of those physical phenomena which we have found to be signs of the condition of the organs within the chest. We have already described the methods of examining the chest by sight, touch, and measurement, and we shall have now only to demonstrate them practically on the living subject. But we have to say something on the methods of hearing, or *auscultation*, and the best means of obtaining the signs which it affords.

In getting the sounds of percussion you will always hold in mind the principles on which they depend; and when you have to compare those of one part with those of another, you will take care that the parts are struck alike, and that the pleximeter,

or fingers, on which you strike, are applied with an equal degree of pressure, and to corresponding parts. Thus, in comparing the two sides in doubtful cases, when you strike on one side on an intercostal space, take care that you strike on the other side on the corresponding intercostal space, and not on a rib. And when you strike on the clavicle remark well on what part of it you strike; for the sternal portion of this bone always sounds much clearer than the humeral end. So also in percussing this or any other part, let the direction of your stroke be perpendicular towards the lungs, and not sideways, or you will get the sound modified, not by the lungs, but by the adjacent muscles or other parts towards which the impulse is directed. It is from neglecting this precaution that beginners sometimes get nothing but dull sounds all over the chest. It is not generally necessary to use much force in percussion; in fact, many of the most valuable results are obtained by gentle mediate percussion in the manner which I before described; but you will remember, from the principles then laid down, that varying the force will give you different results, which in some cases may be usefully consulted. I do not give you any absolute rule whether to percuss with the ends of the fingers, or their palmar surfaces, because both methods are useful in different cases. So also where you want to test the density of a small spot, percussion with a single finger is best; whilst for trying a surface of greater extent, flat percussion with several answers better. In doubtful cases it may be useful to try both. In percussing the regions of the back and shoulders, seek the bony prominences of the scapulæ and ribs; for these transmit the impulse to the interior far better than the thick layers of muscles do. But as the scapulæ are moveable bones, it is quite necessary to see that they are in corresponding places on both sides; and to en-

sure this, and to increase the tension of the muscles, it is well, in examining these regions, to desire the patient to cross his arms in front, and bow his head forwards. At that part of the chest near the humeral end of the clavicle, a most important region for examination, there is often a falling away of the chest; and the more tense the pectoral muscles are made, the further they are removed from its walls: here, then, instead of making the muscles tense, they must be relaxed, by letting the elbow hang close to the side whilst mediate percussion is practised in this region. There are several other little details with regard to the practice of percussion, that you will soon learn by experience, now that you know the principles.

The best posture of the patient for percussion is erect or sitting; and in comparing the two sides both before and behind, you should place yourself right opposite to him, and right behind him. When the patient is lying down, the sound is modified by the matter on which he is lying; if it be a soft feather-bed the sound is more dull, if a mattress or any thing harder, the sound will often be increased, because the elasticity of the contents of the chest is increased by the unyielding matter behind it. Never, if you can avoid it, examine a patient in a very empty room, in the corner of a room, or very near a wall, for the sounds are singularly modified by the reverberation of flat surfaces, and the side nearest the wall will

consequently give too loud a sound. You may in some measure remedy this by drawing a curtain against the wall, which diminishes the reverberation: and this is another thing to be attended to, that drapery hanging near the patient will diminish the length of the sound. As most of the effects of percussion are judged by comparison, the chief object of the cautions which I have been giving you is to take care that any of the external causes of modification may not act unequally on the different parts of the chest. If you can, remove the object of your examination beyond their sphere, by percussing him standing in the middle of the room; but as you cannot always do this, try to equalize as much as possible the modifying circumstances, so as not to affect one part more than another, and you may still get good comparative results.

I do not say much about pleximeters, because I really do not think them generally necessary. If, however, you have a mind to be very well furnished, I recommend you one of this form and size; it is made of boxwood, and the upper surface of its little plate is covered with soft leather to prevent the clacking sound of the fingers. The handle, rising from its rim at an angle of about 45 degrees, is particularly convenient for holding it firm to the chest, without interfering with the percussing fingers. The chief precaution necessary in using it is, to take care that it be applied flat, and not tilted.

Let us now study the best methods of listening to the audible signs of the motions, the *dynam-acoustics*, of the chest.

All these signs can be heard by the direct application of the ear to the chest; and this immediate method of auscultation is so easy and simple that it commends itself strongly to us, and is in many cases used with great advantage. The

sounds proceeding from the walls of the chest are communicated to the ear, and especially to the air contained in the external meatus, and are thus propagated in the most direct and unmodified manner to the organ of hearing. Immediate auscultation is exclusively practised by some, both at home and abroad; and as it is much more easily learnt than the mediate

method, I have no doubt that it will always have its advocates among those who prefer ease to exactness. You will ask me, what is the use of the stethoscope, if we can hear the signs so well without it?

I will tell you first some positive objections to immediate auscultation; and on examining the principles of the stethoscope you will find that it has considerable advantages in many cases. To apply your ear, and consequently your nose, face, and so forth, to the chest of a patient who is dirty, or wet with perspiration, you will allow is not pleasant. To apply it to the chest of a patient labouring under an infectious disorder, is neither pleasant nor safe. To apply it to the person of a young female, whether pleasant or not, would certainly not be proper, and perhaps not always safe. Then, you cannot well apply the ear to some parts of the chest, such as the arm-pit, and below the clavicles, or between the scapulæ, in thin persons. Besides this, you will sometimes have disturbing noises from the contact of your hair or your clothes with the patient's chest; and unless your neck be pretty long and flexible, you will find this *easy* method after all more irksome and fatiguing than the mediate method. Still, in a great many instances, it may be used with advantage, especially in examining the regions of the back, and in young children, where the stethoscope might cause alarm, and could not be steadily applied.

We want an instrument, then, to transfer the sounds from the chest to our ear; and what sort of an instrument should this be? It must be a good conductor of sound; and as we found formerly that the power of bodies to conduct sound will depend on the strength and uniformity of their elasticity, and their capacity to vibrate like the body which communicates the sound, we must have an elastic material, of density resembling that of the sources of the sound within the chest, and of the walls of the chest through which they are transmitted. But the sources of the pectoral sounds vary; some, as the voice and the respiration, or at least the hollower sounds of respiration, are produced in air, whilst in others, such as the sonorous rhonchus, and the sounds of the heart, which we have yet to study, the solids are chiefly concerned: we shall therefore need a varied capacity in our instruments to receive these different sounds. It may perhaps occur to you that as all these sounds have to pass through the solid walls of the chest, their differences must here cease, and their character being identified by being made vibrations of solids, the instrument need only be adapted to these solids. But this view is not quite correct; for the thin and yielding walls

of the chest do not considerably modify the character of the vibrations which they receive. As we found by percussion that they derive the character of their vibrations from the nature of the material which lies under them, so when this material originates a sound, the walls vibrating with it do not materially change its nature, or the manner in which it may be communicated to other bodies. It is thus that one parchment head of a drum transmits its vibrations through the air rather than through the solids to the other head, which, in its turn, although a solid, yet freely transmits its motions to the air. In fact, solids, when thin, instead of vibrating only according to their own molecular elasticity, are carried or moved by the vibrations of the media on each side of them, and their vibrations partake of the character of these media. This is the reason why you can hear voices easily through the thin partition of a room; the sound passes from the air to the partition, and from the partition to the air, and you would not hear any better by substituting for one portion of air a conductor of the same density as the partition itself. I could bring many other illustrations of the same point, but I think I have said enough to shew why our instruments for conducting sounds from the chest to the ear should be constructed with regard rather to the origin of those sounds than to the density of the solid walls through which they pass.

To transmit the sounds originating in the solids within the chest, we must have a uniform solid, and the lighter it is the better, provided it be thoroughly rigid. Now nothing answers to this description so well as wood; and in the light kinds of wood with a stiff longitudinal fibre, such as pine wood, cedar, deal, and the like, we find these qualities in perfection. We formerly heard how well a long rod of deal answered as a conductor of the vibrations of a steel tuning fork. Chladni found by experiment that it is scarcely inferior to steel, glass, and other much denser bodies; whilst it has this advantage over them, that being so much lighter it can be much more readily affected by the vibrations of lighter bodies. Here is a cylinder of deal, about eight inches long and an inch and a half in diameter, adapted to the ear at one end, and through it you may hear most of the pectoral sounds; but those best which originate in the solids, such as the sounds of the heart, of friction, and sonorous rhonchi. You also hear the sounds of respiration and of the voice, but by no means so distinctly as you hear them with the naked ear.

But we want an aerial conductor for these sounds, because they originate in air, and can be best transferred through air. Well,

perforate this cylinder with a bore one quarter of an inch in diameter, so as to make a tube of it; if you then apply it you will have a column of air inclosed in the wood, and now you will find that you have the respiration and the voice sounding much more distinctly through it. But as this column of air is in contact with only a small spot of the chest, it can transmit only the sounds produced under or very near that spot, and you have thus an instrument better for exploring small parts of the chest than the ear can be.

We want, however, also, an instrument which will transfer to us the sounds of larger spaces: the sounds of so limited a spot are often too weak to be heard alone; and besides, it would be very tedious to go all over the chest, *dotting* in this way a quarter of an inch at a time. Well, then, let us enlarge our column of air at the base where it is in contact with the chest, by hollowing out the wooden cylinder into a funnel shape, as you see it in this instrument; and by this you will hear the pectoral sounds much more distinctly than with either the solid or the merely perforated cylinder. Need I explain why? The sounds produced under the whole space covered by the instrument are reflected by the funnel into the central bore, and thus conveyed concentrated to the ear. This also gives the instrument the power of concentrating or magnifying the sounds; and thus you may get them as strong at a distance of several inches, or even a foot or two from the chest, as they are to the ear in close contact with it; nay, in some cases, they are even stronger. But here we have another property required in our instrument, that of reflecting all the aerial sounds which have to be concentrated into the central perforation; and we must think of the shape and material that will do this best. As to the shape, you can easily perceive that a funnel-shaped or long conical cavity, with its apex terminating in the central bore, is the best, because it turns the sound at once in a right direction, without the need of repeated reflections. With regard to the material, we may find bodies that reflect aerial sounds better than wood; such are the metals, glass, porcelain, &c.; and if we wanted particularly to separate this class of sounds from others, these materials would answer best. I have found a stethoscope made with a hollow cone of tin plate or brass answer very well. But these materials are too dense to receive readily the weaker vibrations of the solids of the chest, which are much better transmitted by wood; and wood, although not the best reflector of air-sounds, is quite good enough; for what it does not reflect it transmits: and it matters little whether the sounds all reach the ear by the air, or

partly by the air and partly by the wood, so long as they reach it together, which for such short distances they will do. And this leads me to notice another advantage which light rigid wood has over other kinds of material. I told you in my lecture on sound, that the sounding-boards of musical instruments are made of this substance, because its rigidity enables it to receive the finest vibrations of denser bodies, and its lightness renders these vibrations extensive, and capable of impressing a large extent of air, and you saw this illustrated by experiment. Thus it becomes the means of transferring the vibrations from solids to air; and I may now add, the same property also enables it readily to receive vibrations from air. Hence, with a stethoscope of light rigid wood, all kinds of sound are pretty freely transmitted both by the sides of the tube and by the column of air within; and any stray reflections that fall too perpendicularly to be concentrated into the central canal, enter the solid, and are passed on by it; instead of, as in long metallic tubes, being reflected repeatedly from side to side, until they are converted into an echo, which by its tinkle would confuse the original sound.

You see, then, that light rigid wood is the best material for a *stethoscope* or chest-explorer; and the best shape is a perforated cylinder, hollowed at the chest end into a conical cavity, and the other end made flat or slightly concave to fit to the ear. But we still want sometimes to explore small spots of the chest; and for this purpose we fill up the cavity by a conical perforated plug, which reconverts the instrument into a simply perforated cylinder, which transmits sounds unconcentrated. To make this instrument more portable, the upper part of the cylinder may be reduced to a stem half an inch or less in diameter, leaving only at the top a sufficient width for the ear; or this top may be made separate of a harder wood to slip on and off. Wood is so excellent a conductor of sound, that when once the vibrations are in it, they can be conveyed by a very small body of fibres.

You see, then, that the stethoscope, although a simple instrument, comprehends a good many qualities; the chief of which I will recapitulate.

1. To conduct sound by its solid walls.
2. To conduct and concentrate sound by its closed column of air.
3. To transfer sounds from its column of air to its solid walls, or the converse, when circumstances impede their transmission by one of these ways.
4. To diminish this power of transfer, and contract the field of hearing when small spots are to be explored.

You will find a full description of the

stethoscope, illustrated by a plate, in my work on Diseases of the Chest.

If you are not provided with a stethoscope I should recommend you to get one from a turner of the name of Grounbridge, at 42, Poland street. He knows my rules for the construction of these instruments, and executes them well. Here are a great many stethoscopes of all sorts and sizes for your inspection. Do you see this clumsy-looking cylinder, made of walnut painted black? Do not despise it, for it was not only made by Laennec, but used by him for several years: and by its means he discovered many of those valuable signs which I rejoice to have to explain to you. With this other mahogany cylinder I began the study of auscultation fifteen years ago; it has done me some service; and I have no small regard for it. The only other instrument that I shall notice, is this flexible one, which is like a common flexible ear-trumpet, only shorter, and with a rather larger tube. As you may suppose, from its variable shape, it does not convey the sounds of the chest so simply or so distinctly as the wooden stethoscope; yet when you become accustomed to it, you can really hear pretty well with it, and its flexibility gives it a great advantage in many cases. It conveys sounds chiefly by the closed column of air which it contains; and the manner in which sound is reflected in curves, as I before explained, enables it to carry the sounds easily through its windings. Yet if you try this experiment carefully, you will find that you always get the sounds more distinctly by keeping the tube as nearly straight as possible. It is particularly useful for separating the sounds of the heart from their accompanying impulse, as I shall explain hereafter.

Before we proceed to our practical demonstrations on the living model, I must say a few words on the method of using the stethoscope. It is quite necessary that the instrument should be applied in close contact with the chest and the ear; the least tilting uncloses the column of air, and occasions great loss of sound outwardly, as well as a confusing entrance of extraneous noises. To prevent this tilting, it is best to hold the stethoscope by its pectoral end firm on its base, and then to apply the ear flat to the top. If the inequalities of the ribs leave apertures between the chest and the instrument, a fold or two of linen will obliterate these, or the instrument may be used with the stopper in. For the sounds generally it is best to use the concentrating instrument without the stopper; but when it is an object to determine whether a sound is produced in a limited space or over some extent of surface, the circumscribing power of the stopper is wanted. Thus it is often of im-

portance to determine whether a vocal resonance is produced in a small cavity, or merely transmitted by consolidated lung from several bronchial tubes distributed over some extent of surface. The simply perforated cylinder will often do this by showing the size and shape of the limited spot in which the resonance or pectoriloquy of a cavity can be heard in its full strength, while the bronchophonic resonance is transmitted less strongly, and may be traced over some extent of surface, generally in the known direction of these tubes. The stopper is useful also in shutting out the sound of respiration when it is an object to listen to the sound of the heart or arteries, and in many other circumstances which we shall notice as we go through the diseases which produce them.

In conducting your examinations, try as much as possible to avoid fatiguing or annoying your patient. There are cases in which a complete physical examination will do more harm than the information which it may convey can do good; but they are few; and I must leave it to you to hold the balance between too much and too little examination. You will soon in practice find out, too, that your own ease must be attended to in the act of auscultation; for a constrained or painful posture will prevent you from hearing well, and from attending well to what you hear. For this reason you may sometimes hear better with the flexible ear-tube than with the straight stethoscope, although the latter is, for general purposes, the best instrument.

[The remainder of the lecture was occupied in practical illustrations of the methods of the physical examination of the chest.]

LECTURES

ON

RHEUMATISM AND ITS EFFECTS;

By R. MACLEOD, M.D.

Physician to St. George's Hospital.

LECTURE V.

Pericarditis very rare in Synovial Rheumatism, which, however, may be transferred to the Membrane of the Chest or Head by Metastasis—Cases in illustration—the Eye sometimes affected, but not nearly so often as writers on ophthalmic surgery would lead us to suppose—other Complications which are described in books extremely rare—Tables and Calculations, shewing the Ages, Duration of Treatment, and other circumstances, connected with Acute, Chronic, and Synovial Rheumatism.

It is a remarkable fact with respect to this form of rheumatism—the synovial—that it has very little disposition to implicate the

heart. Of a large number of cases of rheumatic pericarditis which have fallen under my observation, only one has occurred where the synovial membranes had been the seat of the disease; and, on the other hand, in five cases of synovial rheumatism wherein patients have died from the transference of the inflammation to internal parts, the heart has manifested neither the slightest symptoms of disease during life, nor the least appearance of morbid change on examination after death. But I do not wish to draw from this any other conclusion than that such complication must be comparatively rare; and this inference, I may add, is strengthened by a reference to recorded cases; for where they are related with sufficient distinctness to enable us to determine the nature of the previous rheumatism, it will be found almost invariably that if the heart became involved in the disease, the synovial membranes had not been the seat of the primary attack.

Indeed, there can be no doubt that, on the great scale, there is a striking difference between the affections of internal organs in rheumatic fever, and in cases of synovial rheumatism, even in its acutest form. While the former implicates both the external and internal membranes of the heart by *extension*, and this in a very large number of cases, the latter (where it involves an internal part) becomes transferred to the pleura, or to the membranes of the brain, by *metastasis*, and this in but a small proportion of instances. Nor is the immediate result of such internal inflammations less remarkable; for while very few, if properly treated, die during the first onset of rheumatism of the heart, the mortality holds a very high ratio where the synovial inflammation becomes transferred to the serous membranes either of the head or chest.

There are too many instances on record to admit of the fact being questioned, that synovial rheumatism is occasionally associated with an inflammatory affection of the membranes of the brain; but there are various circumstances connected with such occurrence which require particular attention. So far as my experience goes, this combination is much less apt to attend the early than the advanced stage of this form of rheumatism; whereas I think the heart affection is most frequent at the early period of rheumatic fever. Again, the cases which I have seen have not been when the disease has been erratic as regards the limbs, but rather when it has fixed itself in a few joints, or perhaps in one particular joint: such joint suffers severely, and is generally considerably swollen, from effusion within it. After having been for several weeks, or even months, nearly stationary, the swelling may diminish without any obvious cause; the patient having either ceased to take

any remedies, or continuing to use those which had previously appeared to relieve, perhaps, but not to produce any striking effect upon the local disease. Wherever, under such circumstances, any (even the slightest) head-symptom presents itself, it must be viewed with the greatest suspicion.

Sometimes the affection of the brain is manifested by pain in the head, which is at one time acute, at another dull—at one time persistent, and another periodic, or at least paroxysmal, with almost complete remissions. Where there is pain in the head, however slight, attention is generally directed to the part; but occasionally there is no pain whatever, even although the disease has made considerable advances.

The following case may serve to illustrate the peculiarities of one form of this disease:—

A gentleman of literary habits, in the 37th year of his age, had suffered for above two months from pain, with swelling and fluctuation, of several joints, particularly the knees. The right knee was more especially complained of, and there was considerable effusion into the joint, evinced by a soft fluctuating projection on either side of the patella and across the lower part of the thigh, just above the knee. He took acetic extract of colchicum, in doses of gr. iij., and acetate of morphia, which last was increased gradually from $\frac{1}{4}$ to $\frac{1}{2}$ a grain; but without any effect in relieving the affected part. About the end of May, 1837, he complained of his memory being impaired, so that he had great difficulty in remembering words; but he was able to go out in an open carriage, and took a short airing on Sunday, April 2d.

Next day I found him in bed, unable to answer questions otherwise than by the monosyllables "Yes," and "No." He expressed his mortification at this inability to speak, by gestures, and when asked if he had any pain or giddiness about the head, answered "No," and shook his head in such manner as to show that he perfectly understood what was said to him. His pulse was 78, and soft; his tongue clean. No complaint was made of the knee, but on examining it I found the swelling almost entirely gone; indeed all fluctuation had disappeared, and there remained only some puffiness about the parts. He was freely purged, and a mustard poultice applied to the knee.

4th.—The same symptoms continued without perceptible change. Twelve leeches were applied to the temples, and the purging repeated.

5th.—In the early part of the day he seemed better; recollecting his sister's

name, which he had previously forgotten. Late at night was seized with a fit of screaming, accompanied by strabismus affecting the right eye, and followed by frequent moaning.

Leeches to forehead, and gr. ii. of Calomel every three hours. A blister to the back of the neck.

6th.—Strabismus gone, but mouth perceptibly, though slightly, drawn to right side, with much subsultus tendinum, and frequent sighing. Answers questions which require only monosyllables distinctly; says "No," when he is asked if he has pain in the head, and "Yes," when asked if he has any giddiness. Pulse 80, with some sharpness.

Twelve leeches to temples; Calomel, gr. iii. every three hours; strong mercurial ointment to be rubbed in very freely.

7th.—Very little change. Calomel omitted after the seventh dose, in consequence of purging. Mercurial frictions continued every two hours.

8th.—Much more sensible, and expression improved. Urine, which has been rather scanty, has become more abundant. Pulse 78. No mercurial fœtor, but a perceptible red line on the gums.

9th.—Continues apparently to improve; gums decidedly injected, but no mercurial fœtor. Takes beef-tea plentifully. Shows by his manner that he recognizes those about him, but cannot name even those most familiar to him.

Towards evening he began to sink. Frequent starting, and constant deep sighing; pulse becoming weaker, and rising in frequency to 100. These symptoms continued till the evening of the 10th, when he expired.

Autopsy.—The convolutions of the brain were flatter than usual; the arachnoid was injected, and there was a slight appearance of effusion. The ventricles contained from ʒiiss. to ʒij. of clear limpid serum, and each *corpus striatum* had the appearance of being smeared over with a thin layer like cream; but this could not be wiped off, and apparently depended on thickening and opacity of the lining membrane. The convolutions of the left fissura Sylvii were adherent, from inflammation of the interposed membrane, and the substance of the brain on either side of the fissure was of a yellowish colour, with patches like minute points of extravasation. The heart and other thoracic viscera were perfectly healthy. In the right knee, which had been the chief seat of the rheumatism, the membrane was thickened, rugose, and red all round, close up to the cartilages. The membrane had been pushed upwards, so as to increase the extent of the cavity,

but no longer contained any preternatural quantity of synovia*.

Now this is a case to which I have seen several more or less analogous, and evidently consisted in a slow and treacherous inflammation about the brain, producing fatal effects without exciting the general system into any of that sympathy which usually attends the progress of mortal diseases.

In another form of this metastasis the symptoms are more marked, especially as regards the occurrence of pain in the head, by which the seat of attack is clearly pointed out. A case of this kind lately occurred at St. George's Hospital, under the care of Dr. Seymour. A man had long laboured under synovial rheumatism, and there was great permanent distension of the capsules. One day the knees, which had been greatly swollen, were observed to be flaccid—reduced, in fact, by about one-half. He complained at the same time of pain in the head, became paralysed on one side, and expired in the space of 36 hours. On opening the body, a deposit of greenish-looking purulent matter was found smeared over the greater part of the surface of the left hemisphere, and there was considerable effusion into the ventricles. Here the disease had gone on silently up to a certain point, as there was not the slightest evidence of any increased action about the head till the paralysis came on. In yet other cases of this affection, there is pain of the head of several days' duration, afterwards giving place to symptoms of pressure, very much in the manner we see in hydrocephalus. A very good illustration of this is contained in Sir B. Brodie's work on the Joints.

A lad, aged 13, had inflammation of one knee, with effusion into the joint; thickening of the synovial membrane resulted, and the enlargement of the joint continued for several months. At the end of this time the swelling became suddenly reduced, and this was simultaneously accompanied by the supervention of acute pain in the head. This returned several times periodically at night, and after a week entirely ceased, when he became affected with somnolency, strabismus, and partial blindness, in which state he died.

In almost every instance wherein the cerebral affection assumes the insidious form described in the first case, the paralytic attack detailed in the second, or the form of hydrocephalus, as in the third, the attack proves fatal. But in some the disease more resembles common inflammation of the brain, admits of the ordinary active treatment, and more frequently than in the preceding instances also admits of a successful termination.

* This case was attended by Mr. Pereira, Dr. Clendinning, Dr. Hope, and myself.

Dr. Copland has recorded a case in which rheumatism was connected with inflammation of the membranes of the spinal cord; but as in the case alluded to the rheumatism alternated with *chorea*, there is at least room to suspect that it was this last, rather than the rheumatism, which directed the disease to that portion of the nervous system.

Another complication of this form of rheumatism is with pleurisy; and here, too, the internal inflammation depends upon a metastasis, the affection of the joints subsiding, or wholly ceasing, on the supervention of the thoracic disease. I have more than once witnessed this occurrence, and the phenomena were rather remarkable, having given rise to a copious sero purulent effusion into the bag of the pleura. This form of metastasis is quite distinct from that which takes place to the pericardium in diffuse rheumatism. In this last the inflammation may, and frequently does, extend over the covering of the heart to the contiguous pleura; but in the cases of metastasis of synovial rheumatism to which I allude, the pericardium was free from any participation in the disease.

Another part to which rheumatism occasionally extends is the eye; and I mention this here, because I have never seen it except in connexion with the synovial form of the disease. Certainly it is not common for patients labouring under any form of rheumatism, whether acute or chronic, to become affected with ophthalmia while under treatment; and it appears by the best works on diseases of the eye, that the cases which have been called rheumatic ophthalmia are principally instances of inflammation of the sclerotic coat or conjunctiva, in persons who have had no other form of rheumatism. The application of cold and damp, which in one person produces rheumatism, in a second may produce cynanche, in a third bronchitis, in a fourth ophthalmia; and if the latter be called rheumatic, I see no reason why we should not also speak of rheumatic cynanche, rheumatic bronchitis, &c. In order to prove that one disease is of a specific character, and similar to another, we ought to be able to shew, either that they occur together so frequently as to leave no reasonable doubt of their identity—which is the case in rheumatic fever and pericarditis—or that the sudden retrocession of the disease in the extremities is followed by the internal affection, as where synovial rheumatism is transferred to the brain; or, lastly, the internal affection, if it manifest itself first, ought to become mitigated, or to cease entirely, on the disease attacking the limbs—a phenomenon frequently witnessed in gout.

Now if these tests be applied to rheu-

matic ophthalmia, I have no hesitation in expressing my conviction, that the number of cases in which it is met with will be prodigiously reduced; in fact, of nearly 200 patients whom I have treated for different forms of rheumatism in St. George's Hospital, during the last four years, only one has had inflammation of the eye; and I observe that, in a table of 520 cases, given by Haygarth, the eye was only affected in two.

The case above alluded to happens to be, at present, in St. George's Hospital, in a state of convalescence; and it is remarkable that he has suffered, at several different times, from synovial rheumatism, and at each time has had ophthalmia. I would by no means be understood, therefore, as denying the existence of rheumatic, or rather perhaps of arthritic ophthalmia. All I maintain is, that the affection bears a very small proportion to the total number of cases, and that the term has been unwarrantably extended by writers on ophthalmic surgery, to inflammations of the eye having no connexion of any kind with rheumatism except that of being produced by the same exciting cause, viz., cold.

We read in medical authors of various other parts becoming affected with rheumatism by metastasis. One would expect such affections to be more common, in connexion with this, than the other forms of the disease, because it bears a very strong affinity to gout; and gout is proverbial for its erratic propensities. At the same time I must remark, that I have been looking out for such examples during twenty years, at the Westminster Dispensary and St. George's Hospital, and have never met with any unequivocal instance of the metastasis or extension of rheumatism except those I have mentioned above. We have abundant derangement of function in the alimentary canal and kidneys, but as out of many hundred cases, I have never seen rheumatism, when unconnected with gout, transferred to the stomach or the bowels, the kidneys or the bladder, in the shape of inflammation, I think I am warranted in inferring that such cases are of very rare occurrence.

No inconsiderable portion of the subject still remains undiscussed; but the very limited time allowed to these lectures has expired, and I must necessarily leave it incomplete. The Gulstonian lectures* are, or ought to be, connected with the subject of anatomy; and I have therefore considered it my business to dwell especially upon the effects produced by rheumatism, on the various structures which it attacks.

* It may be proper to state, that this and the preceding, though for convenience divided into five portions, constituted the Gulstonian Lectures, limited to three in number, delivered at the College of Physicians last summer.

Had time served, I should, in speaking of the treatment, have ventured to urge the advantage of general bloodletting and purging in the early stage of acute rheumatism, carried to a considerably greater extent than is usually done. Indeed, it is the only method by which I have ever seen the disease extinguished, like a common inflammation.

It would have been an interesting question to have examined the circumstances which give efficiency to particular remedies—stimulant diaphoretics, warm baths, and strong exercise, in some; narcotics, such as stramonium and aconite, in others. To have traced the specific influence of colchicum, where the synovial membrane is implicated, as well as the superiority here of local over general depletion—the use of mercury in the diffuse or fibrous form, its failure in the synovial—and the very remarkable effects sometimes produced by the hydriodate of potass, more especially in almost all those cases where there has been any thickening of the affected textures.

Such are a few of the practical parts which it was my intention to have discussed; as it is, I must content myself with adducing a short tabular view of the cases I have most recently treated, and from which the opinions above delivered have been in great measure deduced. In its present state, however, it is only offered as a unit towards forming a sum from which general calculations may be made at some future time.

Tables and Inferences drawn from 150 Cases of Acute, Chronic, and Capsular Rheumatism, treated at St. George's Hospital during a period immediately anterior to the delivery of the preceding lectures.

25 to 30	15	7	22
30 to 35	8	3	11
35 to 40	8	0	8
40 to 45	3	2	5
45 to 50	1	0	1
50 to 55	0	2	2
55 to 60	1	2	3

From this table it would appear that in both sexes from 15 to 30 is the time of life most obnoxious to acute rheumatism, 54 out of 85 cases having occurred within the period specified.

Periods during which the Cases of Acute Rheumatism were under treatment.

Cured.	Died.
In 5 days 1	Of pericarditis, 2; viz. at the end of three days, 1; at the end of three months, of a second attack, 1.
In 8 days 6	
In 10 days 4	
In 12 days 4	
In 2 weeks .. 7	
In 3 weeks .. 22	[Date of discharge not recorded in 3]
In 4 weeks .. 14	
In 5 weeks .. 3	
In 6 weeks .. 9	
In 8 weeks .. 6	
In 10 weeks .. 1	
In 16 weeks .. 2	

It thus appears that 58 out of 82 cases were discharged cured within a month; and when it is kept in mind that it is the custom of the hospital not to send out patients who have had acute rheumatism as soon as they cease to complain of pain, we may safely assert that the number specified were cured in little if at all exceeding three weeks. But 44, or rather more than one-half, were actually discharged within three weeks; and certainly the great majority of these were free from complaint at the end of a fortnight.

In a small number, perhaps about one-eighth of the whole, the disease was absolutely cut short at once, within two, three, or four days; and in two or three cases it was (even though accompanied by much swelling and redness of the joints) arrested within twenty-four hours. To effect this, however, various concurrent circumstances were required—viz. a constitution previously healthy, a very recent attack, and active depletion.

Of the 85 cases of acute rheumatism above alluded to, the heart was implicated in 18, or rather more than one-fifth.

But of the total number of patients, 55 were males, and only 30 females. Now of the men not more than seven had pericarditis, whereas of the women, eleven, or about one in three, had symptoms indicating that condition.

Of the eighteen cases in which the heart was affected, there was only one in which the pain of the limbs was simultaneously so alleviated as to give the least colouring to the idea of metastasis. In seventeen of the cases alluded to, the heart affection was preceded by rheumatism of the limbs; in one case the pericarditis came on first, and the rheumatism of the extremities subsequently, but within twenty-four hours.

The occurrence of inflammation about

the heart always added to the duration of the case. Thus, of the forty-four discharged within three weeks, none had pericarditis; but of the fourteen who were not discharged till the end of the fourth week, not fewer than five had had the heart affected; and this rule, that they who had such complication required to be kept longer than others in the hospital, held good almost uniformly. Thus of those who were discharged at the end of six weeks, amounting to nine, four had had pericarditis; of those who were eight weeks in the hospital, amounting to six, three had pericarditis. The one who remained ten weeks, and both those who remained sixteen weeks, had rheumatic affections of the heart. The fact of this complication being chiefly in those who remained longest in the hospital must not, however, be understood as implying that the pericarditis supervened chiefly after a certain residence in the hospital; on the contrary, in the great majority of the cases the rheumatism attacked the heart at an early period; while in about one-third of the number the symptoms of heart affection were fully developed at the time of their admission. Again, the prolonged stay of such cases in hospital is in great measure owing to this, that I invariably make it a rule not to discharge them until I have expended every effort to promote the reabsorption of any effused lymph, and to render the action of the heart as quiet as possible. Unless this be done, the damage goes on increasing very rapidly when the patients return to their active avocations.

The following are the ages of those who had rheumatic pericarditis:—

Age.	Males.	Females.	Total.
10 to 15	1	0	1
15 to 20	2	4	6
20 to 25	2	4	6
25 to 30	1	2	3
30 to 35	1	0	1
55 to 60	0	1	1
	7	11	18

Very few children are admitted into St. George's Hospital; but from what I have seen in dispensary and private practice, I am inclined to believe that the proportion of cases of rheumatic pericarditis is considerably greater in young subjects than in those of more advanced years. Of those referred to in the preceding table of cases of acute rheumatism,

but one was under 15 years, and he had pericarditis. Of cases in subjects between 15 and 20, there were twenty; and of them six had pericarditis. Between 20 and 25 there were thirteen; and of them six had pericarditis. After this the proportion diminishes, for while there were twenty-two cases of acute rheumatism between the ages of 25 and 30, yet they give but three cases of pericarditis; 30 to 35 give ten cases of rheumatism, and one of pericarditis; 35 to 40 give eight cases of rheumatism, and none of heart affection.

Cases of chronic rheumatism, } 42
(Males, 26; Females, 16) }

Ages.	Males.	Females.	Total.
15 to 20	2	1	3
20 to 25	2	2	4
25 to 30	4	4	8
30 to 35	3	2	5
35 to 40	3	2	5
40 to 45	1	2	3
45 to 50	5	1	6
50 to 55	2	2	4
55 to 60	1	0	1
60 to 65	1	0	1
65 to 70	2	0	2

So far as this table goes, it would seem to show a remarkable difference between the ages at which acute and chronic rheumatism are most prevalent. In the former instance, from 15 to 30 gave about two-thirds of the entire number of cases; here the same period of life gives only 15 out of 42, or little more than one-third. After the middle period of life, the tendency to acute rheumatism progressively and rapidly diminishes; not so with regard to the chronic form of the disease, which is more equally spread over the period of adult age. Of the acute cases, only 3 occurred between the ages of 45 and 55, or about 1-28th of the whole number; whereas the same period gives 10 cases of the chronic form, being about 1-4th of the whole.

Periods during which Cases of Chronic Rheumatism were under treatment.

1 week	1
2 do.	7
3 do.	7
4 do.	12
6 do.	10
8 do.	4

Date of discharge not recorded 1

In about 3 4ths of the above, the pain was entirely, or almost entirely, removed; in the remaining fourth the disease was

so far mitigated as to admit of the parties being made out-patients.

Cases of *Synovial Rheumatism* } 23
(Males, 16; Females, 7)

Ages.	Males.	Females.	Total.
15 to 20	1	0	1
20 to 25	1	1	2
25 to 30	2	1	3
30 to 35	3	2	5
35 to 40	1	1	2
30 to 45	2	1	3
45 to 50	3	0	3
50 to 55	2	0	2
55 to 60	1	0	1
60 to 65	0	1	1

According to this table, capsular rheumatism would seem to be considerably more prevalent among men than women, and much more equally diffused over different periods of adult age, than the form of the disease first described.

Periods during which the Cases of Capsular Rheumatism were under Treatment.

3 weeks	3
4 do.	3
6 do.	4
7 do.	2
8 do.	5
10 do.	2
3 months	2
4 do.	1
6 do.	1

The most remarkable circumstance in this table is the length of time during which the patients were under treatment, as compared to the other forms of the disease. Of the cases of acute rheumatism, as we have seen, more than one-half were discharged within three weeks; whereas here the number discharged in the same period scarcely exceeded 1-8th. Again, of the acute cases, less than 1 9th remained so long as two months in the hospital; whereas, of the synovial cases, within a fraction of one-half were in the hospital two months and upwards.

In one of the cases of capsular rheumatism, inflammation of the eye supervened, and it is worthy of remark that the same patient, in more than one previous attack, had suffered from the same complication.

In one case (a woman, aged 45), there were symptoms indicating a slight attack of pericarditis, which, however, was speedily arrested by the ordinary remedies.

Of the preceding cases, three were fatal, —viz. one from suppuration in the joints at the end of two months; one from pleu-

risy, at the end of seven weeks; and one from inflammation of the encephalon, at the end of three months.

The cases of periosteal rheumatism which have occurred within the period to which the above relates, amounts to 10; and those of arthritic or rheumatic pain, following the course of particular nerves (all of the lower extremities), to 7; — numbers too small on which to hazard any general inferences.

REMARKS

ON THE

EXTRACT OF BELLADONNA

GIVEN AS A PROPHYLACTIC AGAINST THE
CONTAGION OF SCARLET FEVER.

By WILLIAM MACLURE, Esq.

Surgeon; late President of the Harveian Society.

To the Editor of the Medical Gazette.

SIR,

THE following paper was read by me before the Harveian Society, at its sitting of the 7th of October, 1833. It relates to the subject of the Extract of Belladonna given as a preservative against the contagion of scarlet fever. If you should deem it of sufficient importance to entitle it to insertion in your journal, be so good as to award to it that privilege at your earliest convenience. I have delayed to publish it till now, in the hope of enlarging my experience of the practice which it recommends, and I have only farther to remark, that since the paper was written, I have employed the extract of belladonna as a prophylactic in several instances, and generally with apparent success; though no doubt the subject still requires investigation. The great importance of the subject, and the probable efficacy of the practice, were fully admitted by the late Sir David Barry, Professor A. T. Thomson, Dr. Theophilus Thompson, and several others of equal eminence, who took part in the discussion.

I remain, sir,

Your obedient servant,

WM. MACLURE.

14, Harley Street,
10th Nov. 1837.

I beg to offer to the Society some remarks on the Extract of Belladonna employed as a Prophylactic against Scarlet Fever.

Hahnemann, I believe, was the first

who proposed giving the extract of belladonna to persons exposed to the contagion of scarlatina, as a prophylactic against that disease. I am told that he published his views on this subject so long ago as 1801, but I have not been able hitherto to procure a sight of his work; what he said, however, with regard to the preventive efficacy of this substance against the exanthym in question, does not seem to have obtained much attention in Germany at the time, for I do not find any other author taking up the subject till Dr. Dusterburg did so in 1820*. In Hufeland's *Journal der Practischer Heilkunde* of that year, Dr. Dusterburg relates that during the epidemic prevalence of scarlet fever at Gutersloh, or Gusterslob, in 1820, he gave daily to such children as had not been attacked, from ten to twenty drops of a solution of three grains of extract of belladonna, in three drachms of canella water: and he assures us that none of the children who continued this medicine a week were attacked with the disease, though continually exposed to its contagion. It is also stated, that every child that did not take belladonna, and was exposed to the contagion, had scarlet fever. From this period it would appear that the subject has attracted a good deal of attention in Germany, and a great many physicians of that country have given belladonna a trial, and have reported favourably of its effects, in the way of shielding for a time the constitution against this often formidable disorder. The celebrated Hufeland, in a work written in German, "On the Preservative virtue of Belladonna against Scarlatina," and published at Berlin in 1826, has collected no less than thirty reports of as many German physicians, whose experience goes to confirm his own opinion of the efficacy of this substance in this particular way. The Professor believes that the efficacy of the plant depends upon its power of diminishing the nervous susceptibility of the human system, so as to render it for a time insusceptible of impression from the contagion†.

M. Martini, in a paper published in the 2d Volume, page 371, of the "*Révue Médicale*," also avows his belief in the preservative virtue of this substance:

and M. Ibrelisle, a physician of Metz, who writes in the "*Bull. de la Société d'Emulation*," for April 1823, p. 201, informs us that he has seen twelve children preserved by the belladonna from scarlatina, which had attacked two hundred and six others, in the midst of whom the twelve protected ones resided. Dr. Velsen, likewise, gave the substance in question to two hundred and forty-seven persons, of whom thirty-one only contracted the disease, although they were all equally exposed to its contagion. This physician prescribed two grains of the extract dissolved in two ounces of water combined with a little alcohol; and of this he ordered fifteen or twenty drops to be taken by each person daily. He remarks with justice that the employment of this means being attended with no danger, there can be little or no inconvenience in giving it a fair trial. In the "*Journal des Progrès des Sciences Médicales*," Vol. 1, p. 242, it is stated by Dr. Wagner, as the result of his experience, that comparing those who took the belladonna during the prevalence of an epidemic, with those who neglected to do so, of the former he lost only about *one* in *seventy*, whilst of the latter there died *one* in *three*. He states also that whole villages in Germany have been preserved from scarlet fever by the inhabitants taking the belladonna whilst the disease was raging in one at no great distance from them. I must confess, however, that I do not place much reliance upon the somewhat vague statements and loose experience of the last writer; but there is something more definite and conclusive, as well as more recent, in what M. Scoutetten has reported as being the experience of M. Friso, of Scierck, in his "*Compte rendu des travaux de la Société des Sciences Médicales du Département de la Moselle*," published at Metz, in 1830. M. Friso, who observed an epidemic of scarlet fever in the village of Reimling, canton of Scierck, and arrondissement of Thionville, during the months of December 1828, and January 1829, derived, he relates, great advantage from the belladonna as a preservative means. The mortality here was very great, since out of about one hundred patients, no less than eighty-three died. The extract of belladonna was given to twenty-two individuals, who, although they both

* Gooch's Study of Medicine, vol. iii. page 20. Cooper's Edition.

† *Gazette de Santé*, Mars 1826.

resided and slept with those affected with the disease, were not attacked. Four children, he continues, living in two houses where there were persons labouring under the malady, did not take the belladonna; whilst in one of these houses, three others took it regularly every day. The four children who had not the benefit of the prophylactic became affected with scarlatina, and what is very remarkable, not one of the other three, though they were equally exposed to the contagion, became ill." "I could," adds this author, "cite many other similar examples which were followed with the same results; and now I never hesitate, in my rounds from house to house, to carry with me my remedy, being well assured that I can always arrest the epidemic." "At this date," (23d Jan. 1829.) he adds, "I have no more patients with scarlatina, and recently I have only seen one individual die of it, and this through the fault of his parents, who obstinately refused all aid whether of a preservative or a curative nature*." In addition to these authorities on this interesting subject, it would be wrong not to add that of Dr. Randhaken, physician to the Orphan Hospital of Langendorf in Prussia, as quoted by Dr. A. T. Thomson†, who affirms that by the same means he exempted from the disease in question, one hundred and sixty children who were exposed to its contagion.

These authorities, it will be observed, are all foreign: indeed they all have a German origin. I have not been able to find that any trial has been given to the alleged preservative efficacy of the belladonna in this country; nor, indeed, in the course of my reading have I observed that the subject has been mentioned at all by any English writer, except in a short notice by Mr. Samuel Cooper, in his edition of Dr. Good's Study of Medicine, already quoted; and in another by our learned associate, Professor Thomson, in his Elements of Materia Medica, though from its manifest importance, not only in a scientific but practical point of view, to schools and families, it certainly deserves a calm examination, and ought to be submitted to further experiment, not only in scarlatina, but perhaps also in the other contagious exanthemata.

I have to lament not only this lukewarmness and neglect on the part of British practitioners, but also that my own experience on the subject is as yet extremely limited. Indeed, what I have observed of the prophylactic power of the belladonna would perhaps not deserve any attention, if it stood alone; but when taken in conjunction with the facts detailed by our continental brethren, it may be considered to have a value which otherwise might not belong to it. Such as it is, however, I now beg leave to submit it to the Society's consideration.

On the 4th day of July last (1833), being the second day of her illness, I was called to visit a young lady whom I soon discovered to be labouring under scarlet fever in rather a severe form; sloughing throat, typhoid fever, and delirium, being among the symptoms. She was attended from the beginning by her mother, a hired nurse, her mother's maid, her own maid, and a house-maid, in all five persons, none of whom, I was told, had previously passed through the disease. The patient's brothers and sisters, at my suggestion and request, left the house on the second day of the complaint; her father remained, but did not, during the whole course of the disease, ascend higher in the house than the drawing-room floor, and the men-servants and others remained below, not being permitted to have any immediate communication with the sick-chamber, which of course was on the bed-room floor. By these early precautions all the male individuals of the house escaped.

Recollecting the passage which I have quoted from the paper of Dr. Dusterburg, in Hufeland's Journal, I resolved on testing the prophylactic powers of the belladonna in the persons of my patient's attendants, thinking, with Dr. Velsen, that if it did no good, it could not do any harm, if given in minute doses and with proper precautions. In accordance with this idea, then, from the beginning to the end of my attendance, two of the maids whom I have mentioned, viz. the lady's-maid and the house-maid, regularly took the medicine in the dose directed by Dr. Dusterburg. The event was, in their cases, that, though they never had had the disease, and though they were as thoroughly exposed to the contagion as the other attendants, they completely escaped. Not so with regard to their

* Revue Medicale, 1830, tom. iv. p. 343. as quoted in the "Dict. Univ. de Med." tom. i.
† Elements of Materia Medica.

mistress and the other attendants. The hired nurse, who was a stout healthy woman, and little more than thirty years of age, in consequence, I suppose, of that faith in her good fortune which had carried her through so many dangers, and which is often so useful a quality in such persons, refused to take the belladonna. The apparent consequence of her refusal was, that in a few days after her attendance had commenced, she became affected with the disease, and being obliged to relinquish her charge, she was sent to St. George's Hospital (whence she had been sent to us) through the kind intervention of Mr. Keate.

Again, my patient's mother, who was most assiduous and exemplary in her attentions to her daughter, hoped to escape it, (though she never had had the disease) chiefly, I believe, in consequence of her age, which, I think, was betwixt fifty and sixty; and she also declined availing herself of the medicine. The apparent consequence here again was, that just eight days after the commencement of her daughter's illness, she, too, became affected with the symptoms of the disorder, and was obliged to give up her affectionate attendance, and be attended to herself.

The lady's maid (one of those who took the medicine regularly) during the course of her mistress's illness, was constantly with her night and day, doing every necessary office about the sick-chamber. She, as I said before, escaped the disease, though so much exposed to the contagion. Lastly, the young lady's maid, who happened to be a sort of fatalist in her philosophical opinions, and professed to believe that nothing could prevent her taking the disease if it was fore-ordained by Providence that she should have it, (forgetting that the *means* as well as the *end* are in all cases fixed and foreseen by the Deity) though she reluctantly took the belladonna occasionally, in partial obedience to my prescription and her mistress's injunctions, yet she did not use it with that regularity which seems to be necessary to its full success; for during the convalescence of the two ladies, whilst desquamation of the cuticle was going on in both cases, she was seized with fever and sore throat in a mild degree, with the usual white aphthous crusts upon the tonsils, which are characteristic of an incipient attack of scarlet fever. Dr. Chambers, who was in attendance

with me on the other cases, saw this patient, and agreed with me in thinking that the sore throat was that of scarlatina, and that the young woman would have the disease, though probably in a very mild form. At the period, however, when the eruption ought to have made its appearance on the surface, none disclosed itself, and none ever did appear; and there was no subsequent desquamation of the cuticle, except a very little from one of her thumbs; just enough, perhaps, along with the incipient symptoms, to prove the identity of the complaint. She recovered rapidly.

The following summary will place before the Society at one view the results of this experiment:

1st, The mother and the sick nurse who took no belladonna, and remained unprotected by it, both took the disease, the one severely, the other mildly.

2d, The young lady's maid, who took the medicine *partially*, seemed to remain only *partially* protected. She became affected with the first symptoms of the complaint, but in her case it seemed to be so modified and restrained as not to be able fully to develop itself.

3d, The two young women who began to take the belladonna as soon as it was prescribed, and continued so doing throughout their attendance, (which I may remark was extended to all the three patients) passed through the ordeal unaffected by it.

I require not to be told how fallacious very often such experience in medicine is; and it will be very easy for those gentlemen who may take a part in this discussion to give a plausible (and perhaps true) explanation of the various phenomena which I have detailed, upon the principle of the various predispositions and susceptibilities of the persons who were the subjects of the experiment, to this particular malady; yet, notwithstanding the force of this argument—strong, if my experience stood alone and unsupported—I cannot help considering the result, when viewed as confirmatory of the more extensive experience of our medical brethren in Germany, as very interesting, and fully to justify me in bringing the subject before this Society.

The dose of the medicine which I employed was twenty drops every night of a solution of eight grains of the extract of belladonna in an ounce of dill-water.

I did not perceive that the belladonna

in these cases produced its usual effects on the pupils; nor even "des coliques, de la diarrhœa, des sueurs, et des urines abondantes," which a writer in the *Dictionnaire Universelle de Matière Médicale* is disposed to attribute its prophylactic effects to; but in one of the cases some degree of head-ache and giddiness was complained of, which was probably caused by the narcotic.

Neither did any artificial eruptive disease, similar or analogous to the scarlet fever, and to the occurrence of which, Dr. Hahnemann, upon homœopathic principles, attributes the prophylactic effects of belladonna against the real disease, make its appearance in any of these cases; so that the belladonna, if it really had any effect at all, produced that effect silently and secretly, without evidencing its operation by any outward or visible sign. It would appear, however, from Dr. A. T. Thomson's remarks in the work I formerly alluded to, that this substance really has the effect, in some instances, of producing a scarlet efflorescence on the surface of the body, as stated by Hahnemann; for he states that he has given it as a remedy in hooping cough, and that while the efflorescence continues, the cough remains absent; but that it returns as soon as the redness, with the other symptoms, disappears. But the numerous German authorities whom I have quoted make no mention of the efflorescence being necessary to the protecting efficacy of the belladonna; and, therefore, we may presume that all that is required for the alleged effect is a sufficient influence being exerted upon the nervous system by the narcotic principle of the plant, as shall render it unsusceptible for a time of being affected by the contagious *effluvia*.

REMARKS ON RHEUMATISM.

To the Editor of the Medical Gazette.

SIR,

IN the year 1835, you published a paper entitled "Pathological Remarks on the Diseases of the Encephalon,"—a subject which had occupied my attention from January to December, 1834. I

now offer to your consideration an "Essay on Rheumatism," the materials of which have been gradually accumulating from the summer of 1835 to the autumn of 1837.

In this essay, a survey has been taken of the disease; but its natural history alone is the subject of the following pages. I decline entering on the treatment: 1stly, because it is not intended for the public, whose appetite for wonderful cures incites them to extol him who promises the most; and 2dly, because it is addressed to the profession, who, as a collective body, are the ablest and only judges of what is true in the history of disease. The history of its treatment opens a wide field; and that alone which relates to gastric and intestinal irritation, conjoined with irregularity in the distribution of the blood, is a subject which would afford materials for an essay of itself, as it offers a point of practical interest, involving the considerations of many principles both in pathology and therapeutics. But it is to be remembered, as a general remark, that right treatment can depend only in right notions of disease.

I am, Sir,

Your obedient servant,

J. A. HINGESTON.

48, Finsbury Circus,
Nov. 6, 1837.

The elementary causes of rheumatism are to be sought for, 1st, in the capillary circulation, and 2d, in the mucous surfaces.

1. *Of the Circulating System.*—Irregularity in the distribution of the blood through the abdominal viscera, the brain, or the spinal column, reflects a similar irregularity on the capillary system, and forms the ground-work of rheumatism. This error of the circulation is induced by fatigue carried to exhaustion; and the rheumatism, which may take place, is that of the large muscles, and not of the joints. Muscular rheumatism seems to have its rise in errors of the circulation through the liver—a tardy return of the venous blood from the abdomen; or more often from arterial injection of the brain or spinal marrow (their substance, or more probably their meninges) whereby there are manifested exalted nervous energy and erroneous local sensation. The cerebral disturbance is subacute and

marked; and depraved nervous sensation is the consequence.

2. *Of the mucous Surfaces.*—Irritation, excitement, subacute inflammation, (by whatever word or phrase we denote the disturbance of the mucous surface) of the stomach and intestines, operates in causing rheumatism of the joints rather than of the muscles.

Intestinal irritation is always connected with, and is caused by, or is dependent on, hepatic derangement—there being not merely venous congestion of the liver, but derangement of the biliary function as a marked and essential feature; and it is also connected with erroneous excretion from the kidneys, the urine either being pale and copious, or deficient, with a deposit of the lithates.

This intestinal irritation is induced by excess of nourishment and the habitual use of stimulants; likewise by inattention to the alvine excretion, allowing the colon to become and remain loaded; and especially by over-exertion and consequent exhaustion of the brain, whereby the stomach is deprived of its proper supply of nervous energy: in which state an attempt is made to revive the stomach by stimulants; but the stimulants cause excitement, with subsequent exhaustion and final disturbance of the mucous surface.

This form of mucous irritation is presented to us in the shape of subacute inflammation (gastritis), and is to be recognised by its usual symptoms as set forth in systematic works. This form, likewise, enters largely into the history of many maladies at their inceptive stage—of fever or indigestion, of visceral inflammations or cutaneous eruptions: it is at the root of rheumatic inflammation, whether acute or chronic.

But the mucous surfaces sympathise particularly, 1st, with the skin, and 2d, with the heart.

1. With the skin the closest sympathy subsists, and is the most visible in those whose skins perspire the most readily. Such persons are the most susceptible of rheumatic attacks; viz. those whose skins and mucous surfaces are excitable and prone to excess. The functions of these two surfaces are reciprocal, and the reciprocity between the skin and kidneys is familiar: so that, the skin, the mucous surface of the alimentary canal, and the kidneys, form a united chain in the causes and cen

operations of rheumatism. Cold suddenly applied to the skin, the changes of the weather, the decline from summer to autumn, are outward causes, operating on the sympathetic chain already noted. It most commonly happens that the mucous surface is already in a state of derangement or excitement when suddenly exposed to the effects of atmospheric changes, and is thereby rendered apt to evince its own derangement by disturbance of some remote organ or texture.

In common medical conversation too much is imputed to the liver, which has borne the burden that ought to be thrown, in part, on the mucous surfaces as well as on the liver itself, and frequently on the mucous surface of the stomach alone. The liver becomes involved secondarily: for the mucous surface of the stomach itself is never deranged long together, without at length implicating the hepatic function, and as soon as the liver is disturbed the stomach rights itself, and leaves the derangement of the liver prominent and alone. What are called "bilious attacks" begin generally in subacute gastritis. The mucous surface, thus subacutely inflamed, generates acid; slight rheumatism is caused by an acid state of the gastric fluid, and cured at once by neutralizing the acid. Whatever diet causes the gastric fluid to become acid, does, in some persons, induce rheumatism.

Rheumatism and gastric irritation co-exist and synebronise.

2. With the heart the sympathy is most immediate. The heart sympathises with irritation or excitement of the mucous surface of the alimentary canal more quickly than it does with the excitement or derangement of any other structure whatever, except the mucous surface of the air-tubes. The mode by which the heart makes known this sympathy, is by its acting irregularly, and distributing the current of blood through the capillaries with irregularity, or if the capillaries be endowed with independent vitality and action, then the circulation is irregular while it traverses these small vessels: but, according to either explanation, the current of the blood flows with irregular velocity. This is a pathological connexion between the heart and arteries, and the mucous surfaces.

Thus we see that the mucous surface of the stomach and intestines holds an important post in the functions of health, and that its disturbance, conjoined with that of the heart and arteries as above noted, forms the platform and elementary frame-work of rheumatism.

To describe the functions of health, we have only to regard the established truths of physiology. The functions of the stomach and intestines, of the brain and spinal marrow, of the heart and arteries, and of the skin, are among these established truths. On the contrary, to describe the erroneous functions of disease, we must watch and observe those errors at the bed-side, and carefully note their respective departure from the natural standard of health, and their sympathy, mutual correspondence, and inter-dependence with the one upon the other. Few, if any, diseases attack one organ without involving the integrity of other organs; and this connexion of one organ with another is different in different diseases, though in each disease that connexion, to whatever extent it may proceed, constitutes at once the respective base and outline of the disease itself. This connexion is to be learned from bed-side practice. The moving circular chain of diseased action stops at the point of death; and the dead-house reveals the still-life, not the movements of the living being—the last impression, not the train of successive operations by which the impression was fixed. There are many symptoms of disease which perish long before the hour of death; fleeting ailments, transient interruptions to life, which the physician is bound to understand and relieve upon the spot, but with which the morbid anatomist can have no concern.

In the foregoing preamble, I have endeavoured to confine my pen to the known truths of physiology and the conventional language of modern pathology. A time may yet arrive when the pathology of the present day shall be as dark to others yet to come, as the infantile pathology of Sydenham is now to us. But in our progress through the wilderness, we must be content to use the language of the natives, as we pass.

Rheumatism has shewn itself to me in three forms:—1st, adventitious rheumatism; 2d, rheumatism of the joints; and 3d, rheumatism of the muscles.

There are several other shapes in which it is met with: such as, senile rheumatism, mercurial rheumatism, &c.; but each of these will be found to include itself under one or other of the divisions above noted.

1. *Adventitious rheumatism* is that form which is met with of an uncertain and passive kind. There is a wandering and rheumatic pain of the large muscles, or of the joints, or of the loins; sometimes slight in degree, and sometimes sharp and disabling, especially in the muscles of the back. It gradually increases from a slight pain to rheumatism of some severity, and is always connected with derangement of the chylopoietic viscera. There are languor, hypochondriasis in the male, and hysteria in the female; indigestion, costiveness, a loaded tongue, and turbid urine. This form is very common, and during sudden changes of the atmosphere presents itself daily to the notice of the practitioner.

It is likewise induced by modes of life. The close, heated counting-house; the sitting upright on a stool from morning to night; the want of sunshine and the breath of heaven; each of them tend to mar the perfect aeration of the blood through the lungs, and to obstruct the return of the carbonized blood through the vena portæ system of vessels; hereby causing (among other evils) perpetual derangement of the chylopoietic viscera, and teasing rheumatic pains. The gay modes of life, in an opulent city, are not less deleterious. The late dinners and the late hour of retiring to rest; the daily use of wine, or of several wines, at one meal; the hot, close, lighted apartments; and the exhalation of the animal spirits, at midnight, when the body ought to be in bed and asleep, equally shake the tripod of life, namely, the brain, the heart, and the lungs, as well as derange the mucous surface of the bowels. Many diseases, besides rheumatism, are traceable to the well-furnished dinner-table: arterial injection of the membranes of the brain, visceral inflammations, bronchial turgescence, defective excretion of the kidneys, and the manifold forms of dyspepsia.

Simplicity of diet, however, is not always to be found apart from a metropolitan life—I have seen those from the country who suffer from similar evils; they exhibit the yellow conjunctiva, the engorgement of the abdominal viscera,

the excess of nutrition, and the rheumatism of the shoulder and loins.

Fixed and chronic rheumatic pains of certain parts, as well as muscular pains of a more transient character, are indicative of visceral organic disease, or of severe functional disorder:—

1. Every one knows that rheumatism of the right shoulder is a prominent symptom of organic disease of the liver: it is even a symptom of functional hepatic derangement. Likewise, derangement of the duodenum gives rise to rheumatic pain of the shoulder joint. Pain in the muscles of the loins is sometimes the only announcement of engorgement or incipient inflammation of the liver.

2. Rheumatism of the left shoulder and arm, and of the left shoulder-blade, is one among the signs of organic disease of the heart.

3. Rheumatism of the intercostal spaces accompanies the early development of tubercles in the lungs; and acute spasmodic rheumatism of the muscles of inspiration marks the locality of a tuberculous excavation: this rheumatic pain may be mistaken for pleurisy or slight peripneumonia.

4. Rheumatism of the anterior margin of the temporal muscle, of the levator palpebre, and of the superior oblique muscle of both eyes, or of one eye, is a common symptom in indigestion, or rather of that gastric irritation when acid is formed on the stomach, and when the colon is surcharged or disordered. Rheumatic crick of the sterno-mastoid muscle, and of the scapular portion of the trapezius, has its rise from the same source.

5. There is a rheumatic pain of the scalp which I have had reason to connect with subsequent disease of the brain, with apoplexy itself, or with apoplectic turgescence. In one case in which it happened asthenic paralysis followed. Is there ossification of the arteries at the base of the brain, or mere turgescence of the sinuses? There is a fixed pain over one orbit (it is not rheumatic, though it be similar to rheumatism) which, when connected with general derangement of the health, emaciation, and a quickened pulse, is said to indicate tubercles on the membranes of the brain(?)

6. Chlorotic females often complain of rheumatism, and they trace it along the large muscles, or they point to the

shoulder-joint. But chlorosis never happens without biliary derangement, there being a feeble and deficient action of the liver, nor without derangement of the mucous surface of the stomach and bowels; which we know to be a primary source of rheumatism.

7. Whatever disturbs the circulation, so as to alter partially and occasionally, and irregularly, the total current of blood, becomes a cause of rheumatism; and thus it is, that organic disease of the heart or arteries, by interrupting the equable jet of blood throughout the body, is a known and common cause or concomitant of rheumatism. In my opinion it is very probable that organic disease of the heart is at the root of inveterate chronic rheumatism; at least I have detected disease of the heart in cases of long standing. If the heart be diseased, the defect at the centre of the circulation would seem to throw the error upon the circumference of the circle. I have observed that confirmed organic change in the heart or large vessels, always causes, or is connected with, gastric disturbance, which again becomes a reflect cause of rheumatism.

Cases of rheumatism, however, do occur without the slightest previous derangement of the health. Two cases of this kind I have seen, one of which I treated. The first was pure fibrous rheumatism of the shoulder, from sudden exposure to a cold blast, after having been heated by riding hard; and the latter (which I treated) was muscular and fibrous rheumatism, from the top of the head to the sole of the foot, in a strumous youth who had rowed up the Thames to Richmond, and was drenched to the skin with rain while in a profuse perspiration. In both these cases mucous irritation quickly supervened. In the latter, there was neither pericarditis nor any approach to it; and the case recovered, after the suffering and close medical treatment of several months.

The most inveterate and afflicting rheumatism is that of spirit-drinkers, or those who are addicted to dram-drinking. It accedes slowly, becomes most energetic towards the decline of life, seizes different joints or muscles, persists for a long time, resists every mode of treatment, and at length cripples the patient. It successively assaults, ravages, and disables the large and small joints; and attacking the flexor tendons and the muscles of the back,

contracts and distorts the back, a leg, or the fore-arm. These unhappy chilly mortals bake themselves before the fire, exhibit a brown oily skin, a shrivelled aspect, and a moist, red, glazed, cracked tongue, a sure indication of organic change in the stomach. There are hypochondriasis, profuse excretion of urine, and muscular debility; there is often œdema of the feet—the forerunner only of anasarca and ascites. In such cases visceral organic disease is always discoverable.

To every disease there is a physiognomy, an attitude, and a gait; and the practised eye discerns the nature of a malady the moment it looks into the sick chamber. Compare the guardsman, who, in the maturity of age and strength, sits as a model to the pupils at the Academy, with the same man prostrate with the anxious aspect of rheumatism, or with the bended back, the lank form, the ominous flush, the bitter smile of phthisis. Other diseases are equally cognisable: who does not know the dull, red countenance of fever; the visage of exsanguineous exhaustion; the sallow haggard expression of scirrhus? So distinct is the physiognomy of disease; and as distinct is the physiognomy of health, from robust manhood down to a strumous boy!

Second form.—Rheumatism of the joints. This form is generally manifested with acute fever, and its history is to be found in every practical work on medicine. The object of this paper forbids me entering on its history at large: it is my intention to note only particular conditions of the body in connexion with a particular disease.

There is one remark on the nature of acute rheumatism which cannot be overlooked: namely, that its inflammatory condition is not the same as that of adhesive inflammation. For these reasons: 1st, it is not curable by bleeding and mercury; 2d, it does not run the same course as adhesive inflammation, when left to itself; and 3d, it is curable by quinine, which is the very antagonist to blood-letting and mercury. Two distinct inflammatory diseases which are not curable by the same remedies cannot be the same inflammations; but rheumatic inflammation is curable by different means to those by which adhesive inflammation is cured; therefore adhesive inflammation and the inflammation of rheumatism are not one and the same.

The only time when the remedies for adhesive inflammation are requisite, is when pericarditis supervenes; but if any one would attempt the cure of acute rheumatism of the joints by vigorous blood-letting, he might drain the body of blood before he accomplished his end: whereas quinine, the very opposite to blood-letting, will establish a cure.

In this manner, the nature of diseased action may be tested by the treatment; and in this instance an important discrimination is drawn which involves the grand principle of right remedial agency.

I have never witnessed an attack of acute rheumatism in which I have not discovered direct irritation of the mucous surface of the bowels, and marked biliary derangement; and also that, in most cases, an attack of acute rheumatism has been forming during several previous weeks or months, by loss of appetite, indigestion, erroneous alvine excretion, depraved urine, insomolence, and lassitude. During the attack, the skin acts profusely, the perspiration is acid, and alternates with the urine; but it is not critical. After a time the skin becomes morbidly dry and scurfy; and debility of the mucous surface of the stomach and bowels follows—a debility which resents the exhibition of tonics, and persists for a long time.

It is with this form of rheumatism, viz. rheumatism of the fibrous tissues, that pericarditis is most frequently associated. Neither my ear, nor my eye, nor my intellectual sagacity, enable me to discriminate between *pericarditis* and *endocarditis*. I recognise the excellent distinction drawn by M. Bouilland as a pathological truth, but it fails me at the bed-side. Time, however, may render me an adept. I discover only inflammation of the heart or its investing membranes. But my experience enables me to affirm that pericarditis is not *always* present in acute rheumatic fever; though I believe it to be more frequently a concomitant, in some degree of intensity or shape, than is generally suspected. By a practised eye its presence is recognized in the physiognomy and posture of the patient; and its existence is certified by the ear. The pulse is no guide to the detection of pericarditis, if it be relied on alone; neither is the tenderness of the intercostal spaces over the cardiac region any absolute criterion, inasmuch as the muscles of those inter-

costal spaces may be rheumatic, and therefore painful. In other acute diseases besides rheumatism, I have remarked, that when the velocity of the heart's action is greatly increased, the external surface of the chest over the apex of the heart has been tender, without there being discoverable any pericarditis. Does this tenderness arise from the muscular structure of the heart becoming tender through over-exertion, or from a blood-shot condition of the heart or its membranes from the same cause—a vascular condition short of inflammation? The same patients have likewise expressed uneasiness or slight pain in that region. To be certain of pericarditis, the ear is the only guide, provided that the ear has been led to the *particular signs* when the eye has recognized the *general symptoms*. When associated with the pathognomic signs in general, the total departure of the heart from its healthy action—its tumultuous irregular pulsations—the whirring sound—and the progressive remoteness of its beat—can never be mistaken.

But though pericarditis does not always accompany acute rheumatism, yet, I think, repeated attacks of chronic rheumatism, with venous congestion or arterial injection of the brain or spinal marrow, seldom originate except in organic lesion of the heart or large vessels. Concentric hypertrophy of the left ventricle, or disease about the mitral or aortic valves, seems to be the leading organic change. Hypertrophy of the right ventricle does not seem, (to me at least) to be so frequent a cause of rheumatism, but venous congestion of the liver is a close, if not constant, attendant on hypertrophy with dilatation of the right ventricle—indeed so close and prominent that I have known the hepatic derangement to be mistaken for the primary disease. Likewise with eccentric hypertrophy of the right ventricle, the brain and spinal column escape; whereas the pulmonary circulation becomes involved, and the patient eventually dies of asphyxia.

The morbid anatomist must do me the favour to recollect, that these observations which have been made at the bed-side are submitted to his judgment, and the undeniable facts of the dead-house.

There is one point upon which my mind is not resolved: it is, whether peri-

carditis arises from metastasis of rheumatism, or whether it forms a part and parcel of the disease itself. I have seen it happen without any retrocession of the inflammation from the joints; and I have seen it happen when the disease about the joints has been cured, or at least has disappeared. No anatomy can help us in this dilemma; which is one among the questions that remain open, concerning the very many maladies that arise and terminate without a fatal issue. Upon these cases we must pronounce judgment from the best evidence that we can collect, and this evidence can be taken only from the passing features of disease during life.

So awful is the propagation of unintentional error under the aspect of scientific truth, that I often pause to consider, lest a very fact should be distorted, discoloured, or obscured, by passing through the atmosphere of my mind. Since having committed the foregoing remarks to paper, my views have been corroborated by a fatal case, the dissection of which rests upon the testimony of Dr. Bull, of Finsbury Place, and Mr. Squire, late house-surgeon to St. Bartholomew's Hospital, as well as upon my own. It happened to a patient about 36 years of age, an inveterate drinker, and a man of gross habits, and ferocious temper. There had been disturbance of the alimentary canal for a long time past, and I had occasionally attended him during three or four years for transient rheumatic pains, gastric irritation, and exalted circulation. This last October he was seized with acute fibrous rheumatism, which yielded to moderate venesection, calomel and opium, and quinine. The heart was carefully watched throughout the ten days of his illness. On the 8th Nov. its action became tumultuous; and on the 9th, while the gums were still sore from mercury, there was precordial pain, and the sounds of the heart became irregular, tumultuous, and remote. There was recession of all outward rheumatism, and he died suddenly on the 10th. On the 11th he was dissected. The pericardium was externally vascular and fat: within, it was in a state of incipient inflammation, and contained about half an ounce of sero-purulent fluid. The heart itself was of formidable dimensions; its coronary veins as well as its substance turgid with blood.

Dark gramous blood filled the right auricle and ventricle, and the walls of the left ventricle exhibited concentric hypertrophy. The margin of the auriculo-ventricular opening, with the folds of the mitral valve, was prominent, rough, vascular, and cartilaginous, and so were the valves of the aorta, to a degree verging close on ossification. It is remarkable that he did not bear venesection well, and the six leeches which were applied to the chest on the 9th, on account of the supervening pericarditis, caused great exhaustion from only a slight hæmorrhage.

In this case we behold the march of rheumatism, viz. frequent alimentary disturbance, acute rheumatic fever, gastric irritation, retreat of the outward rheumatism, pericarditis, and (discoverable after death, and prognosticated before dissection) long standing organic disease of the valves of the left side of the heart.

3. *Rheumatism of the muscles.*—Systematic works do not dwell upon this form of rheumatism with the attention it deserves. Dr. Marshall Hall, the latest writer on the Theory and Practice of Medicine, has omitted it in his classification of rheumatism, or else includes it under meningitis of the spinal column (see § 1338, 1339, 1340, Principles of the Theory and Practice of Medicine, 1837,) which, I believe, is its true connexion.

Rheumatism of the muscles is by no means unimportant, nor does it seem to arise as a symptom of deranged stomach only, though it be, like each other form of rheumatism, accompanied with such derangement.

It accedes in a distinct attack upon the broad or long muscles, and often seizes on those of the back, or of respiration. The pain is acute and spasmodic, accompanied with slight fever, a slightly accelerated pulse, costiveness, broken sleep at night, and weariness in the day. Changes of the weather, unusual fatigue, a too stimulating diet, and a liability to gastric irritation, seem to be its predisposing causes. But there is another fruitful source of rheumatism in this form—defective nutrition. In this metropolis there are those whose minds are so intent on the occupations of the day, that they forget fatigue and cold, necessary repose, and the natural calls of hunger. With the body undefended, and the brain often exhausted,

the muscles are called into powerful exertion, and the stomach is silenced with nothing but scanty and distant rations. The brain is worked to the utmost, and the heart labours to supply the undue nervous energy by an undue jet of blood. The fatigued muscles demand a greater supply of nourishment than the stomach is enabled to cook, and the meninges of the cerebro-spinal system become, at the same moment, exhausted and subacutely injected with blood. Meningitis is a consequence of this state of things.

Such a pathological condition of the body I have had occasion to note. I have seen the pale expressive countenance, the keen and fluid eye, the jaded figure, and the tremulating muscles, worked to their utmost bent. I have seen acute spasmodic rheumatism in such a patient, and arising from such causes.

Notwithstanding the gastric irritation, and the general inflammatory diathesis thus acquired, the urine remains clear, perhaps more abundant than usual, while, at the same time, the skin is prone to act with excess.

Its most distressing mode of attack is that upon the muscles of respiration; and I have seen a patient so seized as to be unable to raise himself from his bed, and unable to breathe without pain and anguish, until he was bandaged, as it were for broken ribs.

In examining the circulating system, the heart and arteries will be found to be slightly accelerated and beating with increased force. The brain has evidently been unduly excited by too great an arterial jet, and the spinal column is so distinctly the seat of increased vascular activity, that a tender vertebra may be detected over the point from which the nerves, going to the rheumatic muscles, originate. I have not discovered any pericarditis; but the question has presented itself to my mind, whether there might not exist hypertrophy of the left ventricle—some incipient organic change about the heart or valvular apparatus. If, in such cases, there be any organic change, it will be found, I venture to predict, on the left side of the heart, and not on the right; but as I have no facts to determine my judgment, so the opinion floats only in the form of a fair inquiry.

The nature of this kind of rheumatism is subacute. Its duration is uncertain;

and the extent to which it may involve the larger muscles cannot be foretold. I have known the following muscles simultaneously affected, namely, the lower edge of the latissimus dorsi, the lower intercostals, the scalenus posterior inferior, the quadratus lumborum, the depressors of the ribs, the pillars of the diaphragm, and the external oblique of the belly. Such a case has been one of great suffering.

A peculiar feature in this kind of rheumatism is, that it takes on a periodic character. The attack will come on at a certain hour in the evening with fever; then spasmodic rheumatism of the foregoing muscles, perhaps during one or two hours, followed by copious perspiration and subsequent ease. The same attack will be repeated towards the dawn, and end, like that in the evening, with a profuse acid perspiration. The brain seems to be exhausted by the attack, and profound sleep is the consequence.

I have known such an attack as this more than once.

The nature of the inflammatory condition is that of the adhesive inflammation, for the disease tells under blood-letting and the use of mercury. Now the attack is directed to the investing membranes of the brain or spinal marrow—serous membranes which are the known seat of adhesive inflammation.

Two symptoms direct my mind strongly to the spinal column alone; namely, first, that during and subsequent to the fit, the belly becomes tympanitic, the stomach being distended with air, the small intestines riotous, and the colon inflated; and, secondly, the sphincter ani has been likewise afflicted with spasmodic constriction, and the rectum has become so inert that the excrement has been expelled only with great effort, and even then of a small taper-like shape. There has been no stricture of the rectum; for the bowel has returned to its duty as soon as the rheumatic attack has subsided. Likewise there has been priapism. Now these are symptoms analogous to those which arise in surgical cases of injured spine.

In each attack which I had to treat, the colon has been torpid, and cerebro-spinal system unduly excited.

The three forms of rheumatism which I at first proposed to treat of, namely, the adventitious, the fibrous, and the muscular, are here concluded.

Concerning the rheumatism of *Old Age* little need be said, except that, independent of the universal rigidity of fibre acquired under the load of years, there is often to be found in old persons disease of the aorta and other parts of the arterial system.

But of all the formidable diseases that I have hitherto witnessed, mercurio-syphilitic rheumatism is the most fearful. Like the rheumatism of drunkards, it is inveterate; and though it may be alleviated by appropriate treatment, yet it never departs entirely, and often revisits its victim at unexpected seasons. In its accession it puts on a periodic shape; the exacerbations appear at the evening twilight, and remain visible till midnight. In extreme cases the features are shrunk and sharp, the countenance is pale, the cellular tissue lax, and the skin scurfy. The sleep is light and broken, interrupted with moanings, and frequently roused with a sudden paroxysm of pain. There is wasting, vigilance, loss of appetite, and an accelerated pulse. At the evening appearance of the fit there is fever; after midnight the pain goes away, the fever follows, and repose ensues till the dawn. The next morning is one of ease; the day passes away without much suffering, till the close of the evening, when "the scourge inexorably and the torturing hour call him to penance."

The seat of pain is along the muscles of the limbs, in the joints, and across the forehead. The swellings of the knees, ankles, wrists, elbows, and shoulders, as well as of the joints of the phalanges, are pale, indolent, hot, with a faint blush; such swellings are often connected with periosteal inflammation, and the rheumatic pain is easily confounded with the pain of diseased bone—the most excruciating pain there is.

The disease generally presents itself in a much less terrible form than that which has just been detailed, and is open to the more permanent benefits of remedial agency. The great art is to discover whether it be pure syphilitic rheumatism, or rheumatism from the conjoined virulence of syphilis with mercury. Both forms are relievable by mercury: but the mere syphilitic form is curable by it; whereas the mercurio-syphilitic is at first relieved, and afterwards aggravated by its specific action.

The latter is to be treated on the general principles of restoring health, flesh, strength, and spirits—a long process, often interrupted, and, after all, dependent in a great measure on the patient himself. But in its mildest form, it presents the same periodicity of fever and pain.

When the disease has been aggravated and long continued, under the paramount ascendancy of the venereal poison, permanent contraction of the flexor muscles ensues. A limb is gradually drawn up and bent by the flexor muscles, at first disabled, then fixed, and finally rendered completely useless. This calamity falls on one or more limbs in succession; and I have beheld a patient of this kind exhibit a hideous and appalling spectacle, as he lay distorted in limbs, agonized with pain, mutilated in features, and blackened with the foulest sores.

They who have been once necessarily subjected to a protracted course of mercury, never recover entirely from its effects. A poison has been introduced into the system, and its specific action maintained for a length of time. The syphilitic taint is met by the mercury; but the remedy allies itself with the disease in overthrowing the strength of original health. Under the most careful exhibition of mercury, for a length of time, the alimentary canal can scarcely escape. The powers of digestion are weakened; and the patient suffers, for ever after, from the imperfect play of the assimilative process. This imperfection alone would favour the advance of rheumatism, and much more support it in the march of a disease, of which it forms a leading division. I have certainly beheld these evils from a previous course of mercury to which patients have been severely and unavoidably subjected, and I consider that, independent of the broken constitution at large, there has been partial disorganization along the line of the alimentary canal.

And here I bring to a conclusion my thoughts on rheumatism. Whatever truth or error they may offer to the reader, it rests entirely with myself. My own observations, inquiries, experience, and meditation, have worked out into form the materials as here given; and the materials themselves have been extracted from private practice. I have endeavoured to render them in execu-

tion both minute and concise, and also to shew that disease may be both studied and treated in the chambers of a private dwelling with the same scientific precision as it is within the wards of a public hospital.

It is sometimes objected, that to take too minute a view of disease is an overwrought refinement in medicine. This objection cannot be true. The more intimate we are made with any subject, the more minute our information becomes; and therefore the more correct and the more valuable. The discretion, it may be the difficulty, lies in not allowing the mind to fix itself upon any one particular, whereas the judgment is to be formed upon a consideration of the whole. But that mind which cannot separate and combine the parts of a subject in a single survey, is not only defective for the practice of medicine, but is also in principle unfit for other offices in life—for instance, that of an arithmetician.

The foregoing essay is but a skeleton and outline of the subject. The leading points and divisions are marked out and defined, and the whole is put together in a tangible shape. But I have declined each opportunity, and therefore resisted several temptations, to diverge and expatiate on many collateral and important branches.

SOME ACCOUNT OF MESMERISM.

BY BARON DU POTET DE SENNEVOY.

[Continued from page 340.]

Theory of M. Rostan.

WE believe that the whole of these phenomena belong to the nervous system, all the functions of which were not as yet known; that it is to a modification—to an extension of this system, and of its properties, that the effects we are now treating of must be ascribed.

In the present state of science, every thing leads us to consider the brain as an organ secreting a peculiar substance, the principal property of which is to transmit and to receive volition and sensation. This substance, whatever it may be, appears to circulate in the nerves, some of which are appropriated to motion (to volition); these proceed from the encephalon or its dependencies to the

extremities: the others belong to sensation, and these proceed from the extremities to the encephalon. The first are active, the second passive.

We may consider the following propositions as established:—When we wish to move any limb, our brain sends to the muscles destined to execute this movement a certain quantity of the nervous agent, which produces contraction. This transmission is effected by means of nerves shewn by anatomy; and if we cut them or tie them, it becomes impossible to execute the motion; paralysis ensues. The same phenomenon takes place with the nerves of sensation; if they are destroyed, sensibility is annihilated in the part from whence they proceed. These facts, known from time immemorial, are incontrovertible, and are generally adopted. They had given rise to the opinion, that the function of innervation was an actual circulation. There were nervous vessels *afferent*, those of the will; and *efferent*, which were those of sensation.

The labours of M. Bogros seem to prove materially that which had been previously arrived at by reasoning.

But of what nature is this agent? The researches of MM. Prevost and Dumas lead us to believe that the strongest analogy exists between this agent and the electric fluid. These physiologists have demonstrated that muscular contraction was the result of a real electric shock.

M. Beclard affirmed, that having laid bare and cut through a nerve of considerable volume in a living animal, he had frequently caused the pole of the magnetic needle to deviate, by bringing this nerve in contact with the needle.

It is known by all persons, that galvanism, substituted for the nervous influence, forces the muscles submitted to its action to contract. Galvani and Volta saw and proved the existence of a peculiar fluid which, at a later period, has been recognised as identical with electricity.

It is known, also, that certain animals possess the singular property of secreting, by means of an apparatus fitted by nature for that purpose, a large quantity of the electric fluid, with which they give violent shocks; so violent sometimes as to occasion death to other fish, or even to human beings, within a certain distance of them.

The *Gymnotus electricus*, the *Silurus electricus*, the *Tetraodon*, the *Torpedo unimaculata marmorata*, and many others, possess this faculty.

The quantity of their electric fluid has been appreciated by means of very delicate electroscopes and electrometers. It has been ascertained that this fluid was secreted by the brain of these animals, since by removing it, or the nerves which go to the apparatus, the electric effects were annihilated—a result which did not take place when the organs of circulation were removed.

Thus it is satisfactorily demonstrated, that in some animals the brain secretes a portion of the electric fluid; that muscular contraction may be produced by electric excitation, &c.—a consideration which gives us strong reason to presume that the nervous agent is either electric fluid, or a fluid very analogous to it.

We shall pass over in silence the proofs that might be deduced from acupuncturation and *perkinism**.

“But this agent does not confine itself within the muscles and the skin; it throws itself off with a certain degree of force, and thus forms a real nervous atmosphere—a sphere of activity absolutely similar to that of electrified bodies.”

This opinion is also that of some of the first physiologists of our time—Reil, Authenrieth, and M. Humboldt. This being admitted, all the phenomena of magnetism appear to be susceptible of a plausible explanation.

The nervous and active atmosphere of the magnetiser increased, no doubt, by the impulse of his volition, mixes and is brought into contact with the nervous and passive atmosphere of the magnetised person, which latter it augments to such a degree, that in some cases there seems to be an actual saturation of the nervous system, capable, when in excess, of putting itself in equilibrium with surrounding bodies; and there is no way of explaining by any other

* “I confess I have always been much disposed to think that electricity, modified by the vital action, is the invisible agent which incessantly traverses the nervous system.”—*Cabanis*.

“Organised beings, and especially the human body, composed of the assemblage of a great number of heterogeneous substances in contact with each other, present to us real and complicated electrical apparatus, in which the principle, of which the nerves are the conductors, appears to act in a manner analogous to that of electricity.”—*Physiologie de Richerand*, t. ii. p. 263.

hypothesis the *secousses* sometimes experienced by the patients.

The nervous system of the magnetised person being thus influenced, and undergoing modifications in proportion to his peculiar sensibility, would suffice to explain all the perturbations observable, and would perfectly account for the communication of the desires, the will, and even of the thoughts of the magnetiser.

"These desires, this will, being actions of the brain, it transmits them by means of the nerves, as far as the periphery of the body, and beyond it."

In this sketch the full mechanism of the production of magnetic effects has probably not been unveiled. This hypothesis, however, which does not depart much from the physiological and physical facts generally admitted, would explain, to a certain extent, the greater part of the innumerable effects produced by what is called animal magnetism, and may, perhaps, assist in revealing some of the most astonishing mysteries of animal life*.

Of all the phenomena produced by the magnetisers, a few only were added to the acquisitions of science; for magnetism, as we have already said, was excluded from its pale, notwithstanding the numerous efforts we have recorded which were made to procure its admission. Good works upon magnetism are in consequence scarce, although many books have been written on the subject, as they are, for the most part, the production of men unacquainted with the physical sciences. The first which created any sensation was that of Mr. Deleuze, librarian and professor of natural history at the Jardin des Plantes, in Paris, written with simplicity, but with considerable logical force. It was difficult to reply to it, for the author was a man of high probity and acknowledged science. No one dared to deny the facts which he attested, but he was nevertheless forced to pay the penalty of his veracity. He possessed all the qualifications which entitled him to be a member of the Institute, yet he did not obtain that honour. His *Histoire Critique du Magnétisme* was the cause. It was only from this epoch that the progress of magnetism became manifest. An academical society of magnetisers was formed, for the study of

the discovery of Mesmer, composed of persons of consequence and of some distinguished medical men. M. de Puységur was elected its president. The society published a journal, and from that time the magnetisers ceased to be on the defensive; they now began to attack their adversaries, and to provoke them anew to a serious investigation, encouraged by the favourable opinions respecting magnetism expressed by Ampère, La Place, and Cuvier. This was in 1819. I was then young, and a medical student. A stranger to all the prejudices of another age, I was ignorant that physical facts could be rejected because they were inexplicable, or because they were contrary to received doctrines. Never doubting, however, that truth must be triumphant, I dared, inexperienced as I was, to demand publicly that I might be permitted to make experiments at the Hôtel-Dieu, at Paris. My proposal was immediately accepted, and I had to appear before incredulous persons, who, perhaps, were so in sincerity, because the truth which I announced appeared to them incredible. It would be useless to relate here all the details of these experiments, which have besides been published in a pamphlet which went through three editions, and has never been attacked. It suffices to say that my success was complete; for a patient who had been thirteen months in the hospitals, and who, for a very long time, had had hæmatemesis, which nothing had been able to stop, being subjected to magnetism, in the presence of forty physicians, experienced such marked effects that she quitted the Hôtel-Dieu twenty-seven days after, perfectly cured. In this patient the vomitings, which had immediately subsided on the first magnetisation, returned on its being suspended, and again ceased, without again recurring, when the operation was resumed. This treatment was attended by extraordinary phenomena of somnambulism, and every trial that incredulity could suggest was employed to ascertain that there was no collusion. An account of all the phenomena which had been produced was drawn up, and deposited with a notary in Paris. This account was signed by all the medical men present, amongst whom were Husson, Geoffroy, Recamier, Briche-teau, Delens, &c.

Some time after, I repeated the same

* In giving the above hypotheses, I wish it to be understood that I by no means consider them sufficient to explain satisfactorily the various phenomena.

experiments at l'Hospice de la Pitié. These led to further trials, and it was then that MM. Georget and Rostan ventured to publish their observations; the former in a work on the Physiology of the Brain, the latter in the article *Magnetism*, in a Medical Dictionary, printed in 1823. They were prepared for all the consequences of their avowal. They knew that the philosophic spirit of the age would be strongly opposed to their assertions, but, confident in futurity, they trusted to time for the justification of their opinions.

M. Esquirol, physician to La Salpêtrière, authorized experiments on the epileptic patients, of whom there were great numbers in his hospital; and there also all the magnetic phenomena were produced, in presence of a crowd of medical men, anxious to verify personally facts of so extraordinary a nature. Bicêtre was also the scene of this kind of scientific investigation, but it was principally at La Charité that magnetism was more extensively prosecuted. About 300 medical men witnessed the experiments made by Dr. Foissac—experiments which were conclusive on the greater part of the controverted points.

Nearly at the same period, experiments were being made at Val-de-Grâce. I magnetised there, in the presence of many students and medical men, an epileptic soldier, who experienced very marked effects. A young physician, Mons. Desruelles, attached to the hospital, submitted himself to magnetisation, and the action was so violent that, after a few minutes, I was obliged to cease operating.

Experiments still more conclusive, if possible, took place before M. Broussais and seven or eight other physicians. Dr. Frappart threw into somnambulism a soldier affected by a nervous complaint; and the trials that were made upon him left no doubt respecting the power of magnetism. M. Broussais was so convinced, that he authorized the publication of these facts.

At this period a very decided movement was again observable in the public mind. Works upon magnetism were in request, and acquired a degree of popularity they had never before possessed.

A very distinguished young physician, Dr. Bertrand, of whom science was

too early deprived, established conferences upon magnetism at his own residence, which were attended by many enlightened men. Although his opinions were contrary to the explanations of the magnetisers of that time, he contributed much towards the establishment of magnetism by his philosophic mind, and by his profound researches into the phenomena which have some analogy with magnetism, such as ecstasy, catalepsy, &c.

Many of the members of our parliament employed themselves in spreading magnetism, both by their writings and by experiments. M. Chardel, the Comte de Gestas, M. de Lascases, and some others, opened their saloons to those who were desirous to be instructed in magnetism. Experiments were made upon horses by the Marquis de la Roche-Jacquelin, colonel of a cavalry regiment in garrison at Fontainebleau, which were perfectly successful. The *corps médical* of Paris began to give serious attention to magnetism, and one physician felt sufficient confidence in himself to invite the Royal Academy of Medicine to a new investigation.

The Academy knew not yet which side to take. It contained many individuals convinced of magnetism, and others who desired to be enlightened on the subject; but fearful of suddenly giving too much importance to the magnetiser—fearful even that the nomination of a committee to examine into it would lead to the opinion that it was favourably disposed towards magnetism, it adopted a middle course; it commissioned MM. Adelon, Burdin aîné, Marc, Pariset, and Husson, to investigate the subject, and to make a report by which the Academy might decide whether it could, without compromising itself, appoint a committee for the proposed examination.

These commissioners, faithful to their charge, presented themselves some months afterwards (on the 13th of December, 1825) at the Academy, to relate what they had seen and heard of magnetism. On that day there was a great tumult in the council-room, which did not terminate with the sitting. Three days were occupied in hearing all the opinions, and the Academy at length decided for the investigation. All the members voted on this question, which was considered a very important one,

and there was a majority of ten in favour of those who wished to settle their opinion on the subject of magnetism.

A committee of eleven members was nominated; it was composed of physicians, whose names were as follows:—Bourdois de la Motte (the President), Fouquier, Gueneau de Mussy, Guersent, Husson, Itard, Marc, J. J. Leroux, Thillay, Double, and Magendie. This was a great step towards arriving at a definitive conclusion. By naming the most honourable of its members to examine into magnetism, the Academy forced those persons to be silent who thought it was influenced by sentiments hostile to a truth which seemed to attack received systems.

The committee immediately began its labours by an address to all magnetisers. It invited them to produce, in the presence of its members, the effects they professed to be able to work: some hospitals even were placed at their disposal. Very few replied to this amicable appeal, because this inquiry gave a publicity to those who took a part in it; and although believing in magnetism and practising it, they yet were not willing to put themselves forward, as a failure would have exposed them to ridicule.

The Chair of the Faculty of Medicine of Paris resounded for the first time with the language of magnetism. Professor Rostan pronounced an apologetic discourse on Mesmerism, and on its wonderful effects, in the presence of more than 400 young men. He dared to relate facts which overthrew received opinions, and which justified the assertions of the magnetisers, who were looked upon as enthusiasts.

Lhullier Vinslow, in a treatise on *Materia Medica*, acknowledged the existence of magnetism without any restriction. Professor Segalas, in his private lectures, also undertook the defence of magnetism, frankly acknowledging to his pupils that he had been incredulous, but that having magnetised, he had produced extraordinary phenomena. Marjorlin recommended the employment of magnetism in certain nervous complaints; Fouquier also. Magnetising physicians were then seen for the first time since 1784. At that period it occurred to me to give public lectures on magnetism, and more than 800 young men received instructions,

very imperfect, no doubt, but nevertheless they learned what was meant by animal magnetism.

The antagonists of magnetism did not consider themselves defeated, but they were more timid in their attacks. One alone threw off all restraint: Dr. Virey, a man of *esprit* and imagination, asserted that all magnetisers were imbecile and impostors; but it was a singular fact, that his own works were found to contain the most solid arguments in favour of our opinions; and the magnetisers took care to bring them into notice by means of the press.

Magendie, the colleague of Rostan at l'Hospice de la Salpêtrière, maintained his contrary opinions with less force, and requested to be appointed one of the committee for the examination.

In a subsequent article it will be seen that new antagonists of magnetism arose, opposing the most formal denials to the most positive assertions. But these scientific struggles, which are considered as injurious, are on the contrary favourable to truth; certain names only are compromised by them.

[To be continued.]

HINTS FOR ACCOUCHEURS.

To the Editor of the Medical Gazette.

SIR,

I THINK practitioners do not avail themselves of the advantage which medical periodicals ought to afford, of seeking that information from the profession generally, which their medical acquaintance cannot furnish them with.

I have asked several of my friends, what special reason there is that women should be invariably delivered on the left side. I have got no satisfactory answer from any one, and some treat the bare idea of delivering a woman on her right side as an insufferable medical heterodoxy. It appears to me, that in all common cases the right position has equal advantages with the left, and in many difficult cases superior. I assume that the right hand is generally the most practised and *dexterous*, and (if I may so term it) intelligent. Now where the os uteri is canted up obliquely back-

wards, and there is need of accurate examination, how well does the back of the right hand adapt itself to the concavity of the sacrum, if the patient lie on her right side. Again, in certain transverse presentations, turning will be much facilitated by placing the patient on the right side, and using the right hand.

There is one point more I wish to allude to, which is, the inconvenient mode of passing the female catheter generally practised. I never used to set about the common way with the certainty that I could accomplish it without exposing the patient. This, perhaps, arose from want of natural adroitness—it certainly did not from want of instruction and practice, for I was taught by that excellent lecturer, Dr. F. H. Ramsbotham, and attended the *cours d'accouchemens* of Madame Dutillieux, who (as I was the only English pupil she then had) took me under her especial patronage, and (besides an unusual quantity of *touchés* and speculum practice) insisted on my always passing the catheter "*tout-à-fait à l'Anglais*."

The mode I always now pursue is this. I place the patient close to the edge of the bed in the usual midwifery position; I get a utensil put by the side, and raised nearly to the level of the bed; I easily find the meatus urinaris from its proximity to the vagina; I then introduce a male flexible catheter, and direct the other end over the side of the utensil. The bladder gets thoroughly emptied without further trouble, and not a drop of urine escapes, so that even a napkin underneath the nates is unnecessary. If I experience difficulty, I raise the edge of the clothes, and look, and the patient is not conscious she is at all exposed. Let a person compare this with the ordinary mode, in respect of ease, decency, and cleanliness, and once try it, he will then keep his female catheter for extracting plugs from the nostrils, as recommended by one of your correspondents some years since.

I remain, sir,
Your obedient servant,
HENRY COLES.

Cheltenham Nov. 21, 1837.

GRATUITOUS SERVICES OF MEDICAL MEN.

To the Editor of the Medical Gazette.

SIR,

SOCIETY is divided, I think, by political and statistical writers, into two orders, viz. the *easy* classes, and those others who, as less comfortably circumstanced, may be called the *uneasy* classes. Now I apprehend that the *Medici* family cannot, with propriety, be ranked with any other than the second order. All professions and pursuits have, undoubtedly, their drawbacks and grievances; but the above-mentioned family seem peculiarly uncomfortable and uneasy, and particularly industrious in the exercise of the Englishman's privilege of *grumbling*. I speak, of course, of the masses of each section. Those, of whatever branch of practice, who are well to do in the world, are, as usual, pretty well satisfied with their status, or are at least comparatively so; but the masses, the unhonoured, unbeneficed, unpaid, or underpaid masses, are, as heretofore, uneasy: of this fact, the course of discussion in the medical journals at the present moment affords, I conceive, ample evidence; the uneasy class is, of course, the bulk and body of the profession, and consequently of the reading medical public. The opinions, wishes, hopes, and fears of the uneasy portion of the *Medici* family, are thus pretty fully represented in the medical journals, more especially in those that approach nearest to the character of newspapers. To shew this it would be sufficient, I believe, to glance at the journals of any week or month—for I know not how many weeks, months, or years past, perhaps I might say nearly a dozen, dating from the second or third year of "*The Lancet*," when that journal, determining to swim without the cork of patronage of hospital magnates, threw itself on the masses. But my object at present is not to shew the extent of the dependence of the press on the uneasy professors of the *ars Apollinuris*, but to offer a few observations on the grievances at present most complained of by the profession, viz. gratuitous professional service. This topic has been of late much discussed, in conversation, in medical cir-

cles, and by editors and contributors in the medical periodicals.

Now the question of the policy of gratuitous service presents itself in two forms, more particularly at present, viz. that of affording gratuitously to the Assurance Societies professional statements as to the health of parties desiring to effect insurances on lives; and that of accepting of official appointments of an onerous nature, such as the office of physician or surgeon to a dispensary, without salary or remuneration. As to the first, the grumblers argue, that the private practitioner's statement or certificate of health, usually looked for by assurance societies, in addition to the opinion of their own medical officers, should be given only in exchange for a full professional fee, to be disbursed by the society requiring such statement; and that the prevalent practice on the part of assurance societies of asking such statement without fee, is unjust to the Faculty, of whose members the societies take advantage, so as to enhance the profits of their trade by at least one guinea per policy, at the expense of a too generous and easy profession. And it is held by many highly respectable authorities, that medical men should resist such practices, and in all cases decline answering assurance office secretaries' letters, unless previously themselves *assured* of touching their consideration. Now the whole question between the profession and the assurance offices seems to me to be a question of manner rather than of matter. The question is not whether the medical practitioner should be remunerated by the party indebted to him for whatever he does of work strictly professional, for that cannot be the subject of dispute, and is not really under discussion—nor is the question, whether the assurance office should be reimbursed for its outlay and use of capital, for it is clear that the assuring society are entitled to adequate remuneration. The real question is not by whom or from whose funds, or at whose expense, the private practitioner's statement, so essentially necessary to the continuance of the established system of selection of lives for assurance, if not afforded gratuitously, is to be paid for; it is as clear as light, that the party seeking to obtain the policy, and he only, is bound to pay all expenses: as purchaser, on him must

necessarily, as well as justly, fall all the costs of production. The whole inquiry lies in a very small compass therefore, and there is no question open for dispute but this, viz., whether it is more convenient for the practitioner who will not act gratuitously, that he should settle for his statement with his patient who desires to insure, *directly* or *indirectly*, through the medium of the office. Now, looking to the pecuniary convenience of the Faculty only, the indirect mode of settlement would be much preferable. In that way the practitioner might generally reckon on his fee, at least in all cases in which a policy should be effected. In that way the real biter, if biting there be, would generally be bitten; for the office would, if the fee were considered of any importance to it, raise its charges, and the applicant must (under another name perhaps) disburse the additional 1*l.* 1*s.* But what would be the effect on the mind of the patient of a failure, owing, he might know or conjecture, to an unfavourable statement purchased by the office? or what the effect on the morals and character of the practitioner of the fear of offending a valuable connexion? Take the case of a practitioner requested by a secretary, for a regular fee, to certify as to the health and habits of a wealthy drunkard, opium-eater, or other suicide—of a patient liable, by inheritance or otherwise, to any one of several diseases that frequently occasion sudden or unexpected death: and is such a referee not in a situation of great difficulty? Most would, under such circumstances, risk the custom, and tell the truth: but some might condescend to conspire with the patient, who, in such cases, is often devising fraud against the office, and certify falsely: and in either case difficulty, and probably disadvantage, to the profession would result.

Take now the other case: suppose the practitioner feed regularly by the patient desiring to insure: and how, I ask, is his position mended? Commercially he stands as in the former case, only that he is feed directly by the person that needs the beneficial result of the proceedings in which the practitioner is required to take part. But is he not equally exposed to bias of judgment and suspicion of partiality? If the health and habits of his patient be

unfavourable, how is he to escape the embarrassing choice between good faith toward the office, which by the supposition consults him in confidence, and good nature and friendly feelings towards his patient, and a prudent regard for his own interest as a dealer or practitioner. For my part I have been more than once in the position alluded to, and have therefore practically experienced the difficulty; and the conclusion I have come to after some consideration, and, indeed, repeated reflection on the subject, is, that the practitioner should consider himself as simply a witness, and should be content to answer gratuitously all questions not requiring a personal examination, or re-examination, of the applicant for the policy.

The queries usually put to the practitioner, with one or two important exceptions only, I think all have relation to the past, and run thus:—Has the applicant had this, that, or the other disease, or liability to disease, or habit of life generating tendencies to disease, during your knowledge of him? Such questions fill the paper of inquiries nearly, and may all of them be answered from memory. But then comes a sweeping question, demanding an opinion strictly practical—not an historical statement, viz. is the party a good or bad life for his years? Now this last query, if understood as applying not merely to the past but the present also, may in many cases require a personal examination; in cases, for example, where the medical referee has not professionally examined the party for months, or years, as may sometimes happen. In such instances I readily admit the practitioner is entitled to a fee, not, however, from the office, but from the applicant—not from the vender, but from the purchaser of the policy; and it is against the applicant, and not against the office, that the stand should be made, for he is the party that seeks the benefit of the cost of which the medical referee's fee is an essential part. (*See concluding paragraph.*)

On the whole matter, my conclusion decidedly is that the profession would do better by wholly declining fees for such services.

The advantage of this would be this at least—viz. the practitioner would have, with respect to either party, no temptation to over or understate the facts. I mean, the transaction would of itself, and irrespectively

of previous and extrinsic causes of mental bias, bring into play no sinister interest or feeling that might mislead the practitioner: whether his report were favourable or unfavourable, accurate or inaccurate, as proved by future events, neither party, however affected by the result, could reproach him with more than error of judgment. Applicants generally at once, and the public at large, very soon after the adoption of such a rule by the profession, would come to know that in applying to their medical friends for a statement of health they were asking for a favour which the practitioner might properly, should he see reason, refuse, and which, in granting, he would concede without any lien upon his judgment procured by value received from either party.

The second form of gratuitous service above referred to, is the practice of doing the duty of physician or surgeon to dispensaries without salary or other fixed emolument. Now this case seems to me clearer even than the former. I conceive that junior practitioners are fully justified in seeking dispensary and other gratuitous appointments, and that the profession gains rather than loses by the practice.

I am aware that many disadvantages are alleged to flow from gratuitous labour in this as in other forms, and that the Editor of the MEDICAL GAZETTE has thrown his sword into the scale against the practice under consideration. But I am not the less of opinion, though fully sensible of the weight of opposing authorities, that the practice is, under present circumstances, unobjectionable, and I hope, and am sure, it will be continued. I have been myself a gratuitous labourer for years, amongst the sick of public institutions, and have had occasion to think over the matter many times, and have no doubt that the pecuniary interest of the profession suffers nothing, and that its respectability rather gains than loses by the practice so often referred to.

In the first place, it is an error to suppose that gratuitous labour is less honourable than hired; that the exact contrary is the fact, under parity of circumstances, I am well satisfied. The vicious habits of thought and feeling that have generated the contempt for daily labour and humble industry, so

prevalent amongst all classes of mankind, not excepting even the industrious classes, are conciliated rather than offended by the circumstance that the labour is voluntary, and may be declined at pleasure. It is the commercial pride, the traders' tastes, rather than the pride or tastes of the fastidious gentleman, that revolt against service without pay. Now social rank and respectability are, in this country, infinitely more under the influence of the pride aristocratic than of the pride commercial. I hold, then, that the dignity of physic and surgery is nowise compromised by gratuitous labour in public institutions, but is, on the contrary, better provided for than it could be by any engagements for salary, or other remuneration, that any dispensary, &c. could afford; for I repeat it as a fact, that volunteer labour is, *ceteris paribus*, more respectable and respected than hired labour, even at full wages, and infinitely more so than the same at low charges.

In the second place, the pecuniary interests of the profession suffer nothing by it; and for this position, likewise, I fancy I have good grounds. The truth is, the junior practitioner (I allude to unmixed practice) has to choose between absolute idleness, *quoad* medical practice, and gratuitous labour: lucrative practice is quite out of the question, for many years after his graduation, or before his head is bare, or at least well grizzled. The exceptions to this observation are so few as to prove the rule, and they are attributable, in every instance, to uncommon advantages, and in almost every instance to more than usually effective patronage. The junior practitioner, then, has a powerful motive to induce him to seek unsalaried official employment. He has to escape *ennui*; he has to provide against the inroads of time upon his stores of knowledge; he has to convert into practical impressions his scholastic notions, into skill his mere learning, and, in a word, to complete his education.

In what condition, I ask, do our Universities and Colleges usually turn out their alumni? Are physicians and surgeons finished artists at starting?—or is there any such thing as a physician or surgeon, green and fresh from the University or College, that any man of experience in life would consult with confidence as a competent practitioner?

Certainly not. Nor in asserting this, as I do without hesitation, as an undeniable fact, do I in the least impugn the respected and often eminent persons that preside over our educational institutions; for it is to assert this, and no more, that either the construction of the latter institutions (and not merely the management) is so defective, or else the difficulties impeding their more successful operation are so considerable, that a few years of college or university training are not sufficient for the production of accomplished practitioners. If, then, the young medical man must spend a long apprenticeship or novitiate as a probationer candidate for lucrative practice, as he undeniably must, why, I ask, should he hesitate to prefer self-improvement by gratuitous labour to an idleness wholly unprofitable? It has been alleged, that in this commercial country a craft suffers in popular estimation whose professors, in any considerable proportion, labour without remuneration; and the clergy have been referred to as able to do little, if any thing, for their Protestant fellow citizens, that any other adult and equally well-educated males might not do as well, if parliament had not meddled in spirituals in right of succession to his Holiness of Rome; yet the clergy, it is said, are, on the whole, handsomely paid for their labour, and do no ceremonies or service without remuneration. And the bar has also been cited, as, though enjoying few sinecures, yet nearly quite guiltless of service without pay.

But the question has only, I conceive, been mystified by those references to other professions, placed under very different conditions. The pay of the endowed clergy is, for the most part, a tax paid by all indiscriminately, whether with or without return in the way of service; in fact, a national cess for the use of gentlemen of a certain calling and opinions. The pay of the dissenting and independent clergy consists of free-will offerings under various names, which men may give or withhold, according to their opinion of the value of the service. The lawyers are commonly considered the most rapacious of all; but their work is open, for the most part, to the light of day, and can be judged of, more or less accurately, by all parties concerned, that will be at the trouble of a little attention and in-

quity. Unlike the victims of the doctors' clerical and medical, the barrister's "dead man tells tales." Want of sound learning, or of practical knowledge, in a barrister, cannot escape detection. No ignoramus, and few ungifted men, have attained eminence at the bar: so that if any man of a learned profession is excusable for rapacity, it is the barrister. Yet, if the barrister declines usually to work without reward, it should be recollected that in his case there is and can be commonly no feeling enlisted to give interest to his exertions, but the desire of self-advancement. He is probably ignorant, personally, of his client; who is, further, no object of pity or sympathy in general, but a man in full health in most cases, and often in most prosperous circumstances; sometimes also a branded rogue, oftener an unscrupulous litigant, and at all events he is seldom presented to the practitioner in circumstances to excite compassion, or other emotion of generous interest. How, then, should it be a common practice amongst legal practitioners to work without remuneration? their work, unlike the cure of sickness, excites no popular interest or natural sympathy sufficient for a time to make legal practice its own reward.

Thus the examples of the church and bar are not in point: what then remains in the way of pertinent argument against gratuitous official service? Will it be said that the familiar experience by the public of voluntary unrequited medical labour must tend to cheapen medical service in the general estimation, so as in ultimate effect to lower the average rate of remuneration? But this cannot be said; as I have already shewn that gratuitous labour is more honourable, *ceteris paribus*, than hireling labour. Will it be said that, rather than countenance a practice which many consider at least problematical, for the sake of self-improvement, or other private motive, it would be better to take measures to obtain a home gratuitous practice of sufficient magnitude, an end which I know to be not difficult of attainment in this city? Well, neither can this be maintained by the opponent of unsalaried service, for gratuitous labour is the object of his reprobation; and a practice, whether public or private, that is without reward, is in either case of the character he condemns.

There is one consideration not yet alluded to, which in many minds must weigh heavily in favour of the prevalent practice of junior practitioners rendering gratuitous service in public institutions. It is this: as no class of persons not possessed of competent means could be expected, under any circumstances, to enlist in the public service without remuneration; and as no unpatronized practitioner of pure physic or surgery can hope to cover his annual outlay for years, perhaps a dozen, perhaps many more, by practice alone, it follows, first, that the patients of public institutions usually have the care of the best-educated class of practitioners almost exclusively; and, secondly, that the departments of unmixed practice—viz. medicine and surgery—are filled more nearly, if not exclusively, by men of comparatively independent fortunes, and consequently, it may be presumed, of ampler opportunities and more varied attainments, as well as of more gentlemanly habits. For such persons gratuitous official service affords a resource against the tedium of an otherwise idle life, and a security against retrogression; and, more than that, a sure means of advancement in professional knowledge, and an opportunity of manifesting their practical capacities, which is of no slight value. There is also one other advantage of gratuitous service in early life, that seems wholly overlooked or condemned by the grumblers: it is the tendency that it has to counteract the rapacity so natural to the trader, and so conspicuous in many other professions and callings. It is commonly said by the Faculty, and I believe firmly it is truly said, that no body of men in existence do so much work without receiving or expecting remuneration, as do the members of the medical profession; nor, on the whole, though some grumble, have I seen reason to think that the majority grudge to the poor, or the charitable rich, the gratuitous service rendered by themselves or their fellows. Nor is this an unwise liberality. If medicine is honourably distinguished in a moral view above almost every, or I should say simply, above every other calling, it is so distinguished especially for its disinterestedness. Now if there is any feature of character more advantageous than another, it is precisely that readiness to volunteer service to suffering

fellow men that constitutes, on the part of the medical profession, that disinterested beneficence for which it is so distinguished; and it is inconceivable that a reputation for liberality and humanity, resulting from the daily manifestation of those qualities, should not, directly or indirectly, redound to the advantage of its possessor. It appears to me absurd to suppose that the profession could fail to gain, according to the share of credit it might obtain, for the highly and universally esteemed qualities above named. Indeed, I have no doubt that the maintenance of the old scale of fees (so little diminished, notwithstanding a change of circumstances amounting in some respects to a revolution, especially in the increased number of competitors of superior qualifications, and the diminution of expense and of other difficulties of professional and general education), is not a little owing to the high respect entertained by the public for the medical status and character; to which feeling the practice of gratuitous official service must very considerably, whether directly or indirectly, contribute: so that, to conclude this rather long letter, I have no doubt at all that it is highly advisable that junior practitioners of medicine should accept of unsalaried official practice, and enlist as volunteers, and without hesitation, in the public service, when so circumstanced as to have to choose between a practice not lucrative, and an idleness wholly unprofitable.

In the hurry of writing I find I have omitted one consideration quite pertinent to my argument; it is this:—How will the *protestant* practitioners of Leeds proceed if the assurance offices should meet their threat by a change of mode in transacting business, viz. by calling on the applicant to furnish, or have furnished to the office, a statement of his health such as that in use at present, authenticated by the signature of his medical attendant? In that case it is obvious that those protesters will have the painful choice forced on them, of either refusing their patients, or demanding an unusual fee.

This change of proceeding is obvious and easy of execution, and if adopted will soon shew which is the strongest. Can any one but a medical practitioner doubt which of the parties would have reason on his side? It is not still less

open to doubt on whose side might would be found.

My advice, then, to my professional brethren is this: certify for your patients who seek policies of life assurance, without fee or remuneration of any kind, or from any party; but if you will insist on payment, be cautious how you attempt to enforce it. Appeal to the sense of justice of your patient, or of the office, or of both; remonstrate as much as you will; the more perseveringly you do that, the better for your purpose. But beware of threats; beware of strikes and trades' unions like that of Leeds. To enforce payment from the office would be impossible, as I have shewn; to enforce it from the patient seeking to insure must often be inexpedient. Trust to time and discussion, and avoid the sulks; and in the meantime do not forget your duty to your neighbour, whether the same be a Pharisee or a Samaritan; nor abandon the good old medical practice of rendering service when called on, unconditionally, and pay or no pay.

I am, sir,
Your obedient servant,
MEDICUS.

Nov. 15, 1837.

MEDICAL GAZETTE.

Saturday, December 2, 1837.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri: potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

NEGLECT OF THE SICK POOR.

It is now about three years since the utilitarian faction began to enjoy the long-coveted privilege of treating the wretched, the destitute, and the broken-hearted, according to the maxims deduced from the "population principle." They succeeded in persuading the two chief parties which divide the state, that it would be an admirable thing to allow them to "grind the faces of the poor," and treat indigence with a rigour scarcely deserved by ordinary crime. Nearly all England has now tasted the

bitter fruits of this cruel experiment—such as infanticide, death by cold and hunger, workhouses depopulated by typhus fever, and the blood-stained introduction of the new tyranny into Bradford. Death from neglect of the sick and starving poor has become so common, that we fear the constant recurrence of the same or similar incidents in the columns of the newspapers, will produce a kind of callousness in ordinary readers, and they will turn aside from the detailed account of Englishmen put to death within the dreary walls of some Union Bastile, with the unconcern with which they might run over the list of killed and wounded at a tithe-battle at Limerick or Tipperary. With medical readers the case is widely different. When a homicidal dietary is enacted in a workhouse, it is always with the express or implied sanction of a medical practitioner; when the exhausted labourer attempts to obtain an asylum for a few weeks in an infirmary, it is to some member of our profession that he applies for a certificate; and when he at last reaches that haven where commissioners cease from troubling, it remains for some honest surgeon to unfold the history of the case, and to ascertain, as far as the skill of the dissector may, whether the result was inevitable, or the consequence of Malthusian laws administered in their true spirit—whether, in other words, the deceased was incurable when he applied for relief, or was rendered so by cold, hunger, and ill usage. Hence no one of these cases ought to be uninteresting to a practitioner of physic; and the more frequently they occur, the more ardently ought he to wish the stigma of concurring in the new poor-law to be obliterated from the annals of his profession.

These observations have been naturally called forth by a very painful case

reported in the *Times* of Monday, November 27th. It is an inquest held on Saturday, the 25th, upon the body of Charles Morris, aged 32, who died in the Clapham Union Workhouse, on Tuesday, the 21st. Before commenting on the evidence of the several witnesses, we will just give a brief abstract of the history of the case of the unfortunate patient. On Wednesday, the 15th of November, he applied to Mr. Powis, the surgeon of the Union, from whom he obtained some medicine, and a certificate to be shown to Mr. Burgess, the relieving officer. On Thursday, the 16th, Mr. Powis saw the patient in the workhouse, where he was not admitted, but working at a hand-mill during the day. Friday, the 17th, the patient was reported, by the superintendent of the mill, as too ill to work, but was not seen by his surgeon, and was turned into the streets at night.

Saturday, the 18th. — Patient again not seen by his surgeon, and still not admitted into the workhouse. Sunday, the 19th, ditto. Monday, the 20th, not seen by surgeon; at half-past ten at night he obtained an order of admission into the workhouse. Tuesday, the 21st, is found in the workhouse by his surgeon, in a state of collapse, and dies shortly afterwards. This journal of the case will enable our readers to understand more clearly the evidence of the witnesses on the inquest, as far as it is intelligible. The first witness called gave an account of the appearances on dissection; and though we must confess that his evidence, as reported, is quite unsatisfactory, we are ready to attribute this to the report having been furnished by an unprofessional person. We have no doubt, however, that so good an anatomist as Mr. Solly will think it due both to the profession and the public, to furnish an account of what he really did find in the body of

Charles Morris, instead of the following vaguenesses:—

“Mr. Samuel Solly, surgeon and lecturer at St. Thomas’s Hospital, deposed, that he was applied to, by the parochial authorities of Clapham, to perform a post-mortem examination of the deceased, on Friday; when he found the internal appearances generally healthy, but the cavities of the chest were charged with blood. The appearances were not the result of long-standing disease. The body was not in an emaciated state.”

At the end of the inquest, he was asked whether, from the evidence he had heard, in conjunction with the *post-mortem* appearances, “he could account for the cause of death?” To which he is made to answer, “that the complaint of the deceased appeared to be influenza, and that death was caused from suffocation, by the sudden departure (?) of the fluid into the windpipe. Many similar cases have occurred during the last six months.”

This answer still leaves the *post-mortem* appearances wrapped up in mystery; but by telling us what the disease of Charles Morris probably was, throws considerable light upon the evidence of the others.

The next witness called was Mr. Henry Powis, surgeon and medical officer to the Clapham and Battersea Union. He stated that the deceased called upon him on the 15th November and said that he had a bad cold, which he had caught from sleeping in the open air. Mr. Powis now gave him a certificate to the effect (as appears from the statement of Mr. Burgess, the relieving officer,) that he was ill, but not seriously. Now, the question which Mr. Powis is bound to answer is—what were the symptoms under which this unfortunate man was labouring when he applied to him, after sleeping in the open air in November. What was the state of his pulse, respiration, &c.?

In fact, was he, or was he not, clearly suffering from “influenza,” and in a state in which, had he been a comfortable Battersea shopkeeper, he would have been immediately sent to bed, and visited daily by his medical attendant? The next day, the 16th, Mr. Powis found him in the workhouse, and still thought him not seriously ill, though in addition to his former complaints he now observed that his patient had a large boil upon the inside of his left thigh, which was painful. It appears, that in this agreeable asylum, this test-house for the sick and destitute, they have a hand-mill to grind flour; and strange—most passing strange to say, the said Powis did not think Morris unfit to work at this machine! We certainly had always thought that in every inflammation repose was the first and second and third things requisite for recovery; and that, in so depressing a disease as influenza, severe exertion must be peculiarly dangerous.

The witness did not see his patient again for five days, that is to say, till the following Tuesday, the 21st of November, when, on passing the workhouse in his gig, he was called to by the porter, who told him that Morris was very ill. Having just then an urgent appointment, he was unable to stop, but saw the deceased in about two hours, when he was in a state of collapse. Shortly afterwards he expired. In answer to a question from a juror, Mr. Powis is made to say, “Death might possibly have been the effect of exposure to the night air.” *Possibly*, indeed! We should be glad to know how many persons could stand sleeping in the open air in November, with the thermometer considerably below the freezing point, as it has frequently been during the last month?

We must again repeat that a professional report of the evidence given

at this inquest is imperiously required; for Mr. Powis's evidence, as we find it reported, is not a whit more satisfactory, though somewhat more intelligible than Mr. Solly's. From the patient's account of himself it was clear that he had been exposed to circumstances fitted to ruin the toughest constitution. It does not appear that Mr. Powis took him to be a malingerer; there was the boil, at any rate, plain enough; the symptoms of influenza too, are not obscure; and yet the unhappy patient was set to work at the mill by day, and turned out of the house at night!

Mr. Burgess, the *relieving* officer, was the next witness. He stated that the deceased applied to him on the 15th of November, and asked to be admitted into the workhouse, saying that he had a bad cold in his limbs. The witness gave Morris a medical order, and desired him to bring back a certificate: he did so, and it was to the effect that he was suffering from a bad cold, but not seriously. "He asked the deceased if he thought he could work, who replied, that he thought he could not. Witness referred to the certificate, which stated that he was not seriously ill, when he gave him a loaf, and directed him to attend the board the ensuing day. He said that he had been sleeping at Whitechapel the last few days."

This witness's phrase of "sleeping at Whitechapel" is a good instance of euphemism, or the expressing an ugly thing by an innocent term; just as when Alice Bean, in Waverley, talks of her father's *misfortune*, i. e. his being hanged; for poor Morris's "sleeping at Whitechapel" was, as we have already seen, in fact, bivouacing at Whitechapel, with the thermometer ranging from 21° to 40°.

Mr. Burgess proceeds to state, that the deceased attended the board as di-

rected, on Thursday, the 16th; but it appears that this was only a constructive attending, as the board did not see him, and refused his application on inspecting his certificate. On hearing this decision, Morris asked for a day's work, and was put to the mill. On leaving, he said, "Where am I to sleep at night? I have no lodging. Will you oblige me by advancing me sixpence?"

We do not know what the triumvirate at Somerset House would say to such reckless generosity on the part of a relieving officer; but Morris actually obtained this handsome loan.

About half-past twelve the next day (Friday, the 17th,) Read, the superintendent of the mill, reported that the man was too unwell to work, and had a carbuncle on his thigh.

If we may be pardoned an apparent digression, we would remark, that great writers have so instinctive a perception of reality, that even when they do not draw their descriptions from facts, yet facts seem afterwards to follow their descriptions; so that sometimes Smollett copies nature, and sometimes nature seems to copy Smollett. The poor-law dictators and their understrappers will excuse us, therefore, if we observe, that when they make the sick and dying work till they drop, they are not altogether original; the same feat is to be found recorded in the pages of *Roderick Random*. Captain Oakham, of the *Thunder*, is so indignant at finding that there are no less than sixty-one sick on board his ship, that he determines to diminish the list, and accordingly reviews all the patients on the quarter-deck. They crawl to the place appointed, and as it is settled by the surgeon, under the direction of the captain, that there is nothing the matter with most of them, they are sent back to work.

"Some gave up the ghost in the

presence of their inspectors; and others, who were ordered to their duty, languished a few days at work among their fellows, and then departed without any ceremony."

The third case is wonderfully to the point, and might almost make one forget dates, and imagine that the novelist physician was satirizing a union workhouse:—

"The third complained of a pleuritic stitch, and spitting of blood, for which Dr. Mackshane prescribed exercise at the pump to promote expectoration; but whether this was improper for one in his situation, or that it was used to excess, I know not, but in less than half an hour he was suffocated with a deluge of blood that issued from his lungs*."

In the language of the evidence at the inquest, death was caused "by the sudden departure of the fluid into the windpipe!"

On hearing Read's account, the witness advised that Morris should be employed at lighter work, and that if he grew worse he should be sent to the surgeon. On Saturday, the 18th, witness was in town on duty all day. On Monday night (the 20th), at half-past ten, he called upon the witness. He said that he had been in bed since Saturday, and had been spitting blood. He had an order of admission to the workhouse. The witness, in answer to some questions, put by Mr. Field, clerk to the Board of Guardians, now says:—

"They had no room in the workhouse for the deceased; they are about to build a larger workhouse. The deceased might have gone to the overseer, or in a case of emergency the master of the workhouse can admit a person."

These answers, squeezed out by Mr. Field, are to us quite incomprehensible; for it appeared before that originally the deceased was refused admission on ac-

count of the Board having rejected his application, and not for want of room; and on Monday night, when he had an order, he *was* admitted.

Thomas Read, the superintendent of the mill, deposed that on Friday, the 17th, he made the remark, that the deceased was too ill to work. On that day he had a loaf of bread, and 8d. for his day's work. "About ten o'clock on Saturday, witness's attention was called to him. He scarcely worked a quarter of an hour."

Unless, therefore, the reporter has made some strange mistake, it would seem that after the patient had utterly broken down in the vain attempt to work on Friday, the experiment was renewed on Saturday! Why, this is a step beyond Captain Oakham. "The deceased," adds Read, "came to work about seven o'clock on Saturday morning." On this, the coroner observed, "that when the man was so bad, the surgeon ought to have been applied to." We have next a pauper, who deposes to the deceased tottering as he came along the room where the mills were; and the master of the workhouse, who *now* knows that in an urgent case he can admit a person without an order. The verdict was, "The deceased died from influenza; and the jury cannot separate without recommending, that in all cases of a similar nature prompt measures should be adopted."

Our readers will agree with us, that a more deplorable case, or one less creditable to the parties concerned, has very rarely come to light. Callous, indeed, must be the heart that can weigh the savings produced by the new system against such a catastrophe as this, and exult in the balance of profit! Flimsy, indeed, must be the head which fails to perceive that these melancholy incidents (now, alas! so common) are the plain and inevitable results of the

* Roderick Random, chap. xxvii.

instructions issued by the commissioners, and of the bill on which those instructions are founded. You may know the tree by its fruits, and trace the genuine character of the new edicts in the horrible waste of life to which they have led:

— "scires è sanguine natos!"

THE LATE CASE OF BAYONET WOUND.

To the Editor of the Medical Gazette.

SIR,

IN obedience to my promise, I inclose some observations on the case of bayonet wound, lately brought to University College Hospital. Most of them were delivered last week to the students attending my lectures on surgery, by whom they were received in a style that must have convinced all present, that not a single member of the class is an admirer either of misrepresentations, or of the pretensions of a man to be a judge of surgery, whose ignorance of it is here so fully exposed.

I am sir,

Your very obedient servant,
S. COOPER.

7, Woburn-Place,
Nov. 26, 1837.

Addressed to the Surgical Class of University College at the close of the Lecture on Punctured Wounds, on Tuesday Evening, Nov. 21, 1837.

GENTLEMEN,

IN some numbers of the *Lancet*, recently published, a charge is brought against me of having neglected a man, who lately died of a bayonet wound, in University College Hospital. By a fortunate concurrence of circumstances, this accusation was made only a few days before it became my duty to deliver the lecture which you have just heard on punctured wounds; so that I am enabled to notice the matter on what appears to be a most suitable occasion.

At first I had doubts whether the false, contradictory, and ignorant assertions, made by my assailant, were worthy of any notice, as coming from the foul quarter which they did, and more particularly as in these days every man holding public

appointments, like mine, ought to avoid being too sensitive, or, (as I have heard it expressed) too *thin skinned*. I contemplated also the well known despicable character of the publication, and the little importance which really belongs to any statements made in it. Just as it is desirable to avoid fighting with a chimney-sweeper, not only because there is no honour to be gained by a victory over him, but because any contact with his dirty hide will be sure to soil; so it must generally be expedient to avoid any *rencontre*, or dispute, with a writer, who has nothing to lose, and who, probably, if he had the choice, would prefer any kind of exposure to the decision to leave his aspersions unnoticed.

Some years ago, gentlemen, I used to take in the *Lancet*; but perceiving that it was really itself a *take in*, that one odious purpose of it was to abuse, one after another, many of the most distinguished men in the profession; and that the trash and falsehoods doled out by it every week, instead of being worth any silver coin, were not worth a brass farthing, I soon determined not to be numbered amongst the dupes, who promoted it at the expense both of money and principle. Gentlemen, I can have no hesitation in declaring it as my sincere belief, adopted long prior to the present little *chimney-sweeper* skirmish, that the *Lancet* is a publication completely undeserving of the countenance of a liberal and gentlemanly profession; in which its chief aim is to excite jealousies and discord; to raise undeserving parties into notice; and, by means of falsehood, base insinuations, and the perversion of facts, to lower the characters of almost all the hospital surgeons in London. If one or two of them are made exceptions, in return for value received in the shape of clinical and other communications; if one or two of them are, for the present, not only suffered to continue unmolested, but are actually puffed up to the skies, the day will not be less surely come when their guardian angel will no longer lend them his wings, and they must then either continue to fly of themselves, or fall, like the late poor victim of a balloon-trip, never to rise again.

Gentlemen, as your friend and teacher, I will take the liberty of offering you a few cautions with respect to this publication: place no confidence in it. Look with suspicion on the motives and principles which actuate it. They are not, perhaps, very difficult to scan, even on the present occasion. Waste not a moment of your time, or a farthing of your money on it; and be assured that if you ever suffer your minds to be drawn away from the quiet pursuit of science, and of prac-

tical information, by the glaring nonsense and misrepresentations which it contains, you will never attain eminence or respectability in your profession. I am happy in feeling convinced, from the manner in which you have received my advice and remarks, that you all understand the tricks and roguery of the *Lancet* as well as I do.

Now for an illustration of the mendacity, inconsistencies, contradictions, and wilful misrepresentations of the celebrated agitator of our profession.

"The points of most importance," says he, "are, that the case was *not treated by any one of the surgeons of the hospital*; that symptoms of strangulated intestine set in; and that the cause of the strangulation was not removed.

"On examining the body after death, it was found that the bayonet had penetrated the cavity of the abdomen obliquely downwards, the point of the instrument having just reached the wall of the rectum. *A small quantity of blood was effused into the abdominal cavity*; a knuckle of intestine was strangulated in the external wound." It is added: "*The immediate cause of the man's death evidently was strangulation of the intestine, and not internal hemorrhage or inflammation*!"

Who would believe that the writer of these statements had actually sent his reporter to copy my clinical notes, about a week before the foregoing assertions were published? and that in those notes the following particulars were recorded:—

"When I first saw the patient, between 10 and 11 o'clock of the forenoon following the night of his admission, I found the external wound closed, and a soft swelling behind it, *which, on gentle pressure being made, slowly and gradually returned*." I was then unable to decide whether the swelling consisted of intestine or effused blood.

"The man had been in a state of collapse, with cold skin and cold extremities, a pulse scarcely perceptible, and a pallid cadaverous countenance from the first. Such condition never ceased, and implied the wound of some important organ, with or without effusion of blood, or other matter, into the cavity of the abdomen." I frequently observed, on the same day, *in the course of which I visited the patient not less than three times*, that the pulse and other symptoms indicated extravasation of blood, rather than intestinal effusion, though probably the intestines might also be wounded.

In the record of the *post-mortem* examination, it is stated: "*the cavity of the abdomen was found extensively occupied by effused blood, which amounted altogether to three or four pints. The intestines and peritoneum were*

highly vascular, and in some places lymph was poured out, so as to render the intestines adherent to one another." It is true that a knuckle of intestine had insinuated itself into the wound again; but this had happened subsequently to its reduction in the morning, and probably from the efforts of vomiting. When this piece of intestine had been disengaged, it was found to have been transfixed by the bayonet, and without such lesion of it having been at all discernible in the examination of the inner orifice of the wound, or of that in the muscles under the skin.

"In the progress of the dissection, a wound of the rectum, and another of a vein going into the internal iliac, were detected," whence the copious extravasation of blood had proceeded.

The patient died in less than twenty-four hours from the period of his admission, never having revived from the general collapse. *He had had one motion from a clyster*; and was occasionally troubled with vomiting. When I visited him, about two hours before his death, the sickness had been appeased by opium, and this notwithstanding the swelling had made its appearance again in a diminished form; and as, from the feel of it in the morning, it was doubtful whether it might not be blood, and the man was sinking fast, it was not judged advisable to interfere with it.

Mr. Tayloe, the house-surgeon, justly observes: "The man *died principally and inevitably from the copious extravasation of three or four pints of blood in the abdomen, and the peritonitis thereby excited*. The fact was proved by the trivial change in the condition of the knuckle of intestine entangled in the wound, and the violent inflammation of the peritoneum, more especially in those situations where the blood had accumulated. As Mr. Cooper caused the body to be opened in the hospital theatre, in the presence of Mr. Quain, Professor Carswell, and about 200 individuals, your statement that the man *died of strangulated hernia, and that only a little blood was found in the abdomen*, is at all events known by these numerous witnesses to be incorrect."

Considering, then, that the reporter of the *Lancet* had access to my notes, and actually copied them several days prior to the publication of the foregoing misrepresentations, I may safely leave the world to decide whether the mendacity of its editor has been accidental or intentional.

I have next to prove his ignorance of surgery and pathology. He says, "the immediate cause of the man's death was evidently strangulation of the intestine, and not internal hæmorrhage or inflammation." Like a perfect ignoramus in practical matters, with which I conclude that he

can have had little to do*— * * * *
 * * * * He seems here to be ignorant of the fact, that if the man had really died of strangulated hernia, *death would still have been caused by inflammation.* But, together with that inflammation, there would also have existed certain changes in the protruded intestine, tympanitic distention of the bowels between the stomach and the stricture, a contracted state of the intestinal tube between the stricture and the anus, less severe inflammation in this direction, &c. Now none of these circumstances characterised the case before us, as they would have done, had the protrusion had any share in producing death.

The same ignorance of practical surgery, I remember, was a candidate a few years ago for the office of coroner (great laughter); a place for which he conceitedly appears to fancy himself superiorly qualified on account of his fine *medical abilities.* He rated himself higher however than the public did, and notwithstanding his harangues from carts and ladders, so flattering to the multitude, and altogether so appropriate, he was thrown out. Yet he still fancies himself well cut out for this office of coroner, and in his last number gives a sample of what his talents would be in this way, by putting a few searching interrogatories to me, which, in reality, only manifest still further his own professional ignorance. Amongst them I find this one, "Would mere effusion of blood have produced constant vomiting and constipation?" Constipation indeed! Why the man, as the note-book has recorded, had one motion during the short time he lived: how many would this sapient coroner have desired? According to the rule of practice, no purgative was given, from an expectation that the intestine was wounded.

As for constant vomiting it did not exist; there was occasional vomiting: but *our mock coroner is fortunately ignorant that an effusion of three or four pints of blood in the abdomen, and a wound of the alimentary canal in two places, if he should ever happen himself to meet with these lesions in his political squabbles, would not leave even his stomach, which, I presume, is not a very delicate one, in a perfectly quiet state.* "Where ignorance is bliss, 'tis folly to be wise."

As for some of the *ifs* and *suppositions* which accompany some of his other ridiculous questions, they appear to have been stolen from my clinical lecture, and this will be a sufficient apology for my not commenting on them. Other points have been effectually replied to by Mr. Tayloe.

SECOND REPORT

OF THE

LONDON COMMITTEE OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE,

ON THE

MOTIONS AND SOUNDS OF THE HEART;

Communicated at the Meeting at Liverpool, September 1837.

[For the Medical Gazette.]

THE Committee appointed in London to investigate the motions and sounds of the heart, have to present to the Association a short account of some investigations of the abnormal sounds of the heart and arteries, in which they have been recently occupied, and which were not comprehended in their former Report.

Before describing these, the Committee would remark, that although their inquiries have not been specially directed to that subject, yet they have had many opportunities of verifying the conclusions on the *natural* sounds, as presented in their Report of last year; and these conclusions not having been since shaken by any experiment or rational objection, it may be considered as fairly established, that the first, or systolic sound of the heart, is *essentially* caused by the sudden and forcible tightening of the muscular fibres of the ventricles when they contract; and that the second sound, which accompanies the diastole of the ventricles, depends solely on the reaction of the arterial columns of blood on the semilunar valves at the arterial orifices. It further appears, that the first sound may be increased by an additional sound of impulsion against the walls of the chest under certain circumstances of posture, of increased action of the heart, and of particular stages of the respiratory act. It is also obvious, that the character of the first sound may in some measure depend on the closure of the auriculo-ventricular valves, and on the quantity of blood, inasmuch as these determine the nature and time of the resistance, against which the muscular fibres of the ventricles tighten. So likewise the vigour of the ventricular systole, the quantity of blood propelled by it, the sudden and complete character of the diastole, the fullness of the arterial trunks, as well as the perfect, mobile, and membranous condition of the semilunar valves, will determine the character and loudness of the second sound. An experimental illustration of one of these conditions was observed by the Committee during one of their experiments on the ass—a great diminution of the second sound on the carotid artery being freely divided.

* We have omitted a reference here made by Mr. Cooper to an event not connected with the subject under discussion.—*Ed. Gaz.*

As additional illustrations of the production of a sound like that of the heart, by muscular contraction, the Committee have noticed that accompanying the action of the panniculus carnosus of the ass during life, and the quivering contraction of muscles immediately after death. The sound produced in the latter case, in nature and frequency, closely resembled the first sound of the heart of the fœtus or of small animals.

In investigating the morbid sounds of the heart, the attention of the Committee has been chiefly directed to the causes of those remarkable and various accompaniments of the heart's action, called murmurs, which were happily compared by Laennec with the noises of blowing, filing, rasping, sawing, purring, cooling, &c. This inquiry consists of two parts.

1. *What is the essential physical cause of the phenomena in question?* and 2. *How does the apparatus of the circulation develop this cause in the various instances in which these phenomena are known to occur?* To the first of these inquiries, the experiments of the Committee supply what they trust will be deemed a satisfactory answer: the second is to be answered by extensive clinical and pathological observation, rather than by direct experiment; and although a few physiological experiments will be quoted to this point, yet the Committee do not profess at present to do more than open this inquiry to all those who have the means of pursuing it.

Experiments on the production of Sound by the motion of Water through a Tube.

1. A caoutchouc tube, 18 inches long, and 3-8ths of an inch in diameter, was attached to the stop-cock of a reservoir, in which there was water to the depth of from 8 to 10 inches.

When the water flowed perpendicularly through this tube (the air being first expelled*, and the lower end of the tube kept under water in the recipient below), no sound was heard; but on pressing any part of the tube, so as to diminish its calibre, a blowing sound was heard at and below the point of pressure, and this sound became louder and more whizzing as the pressure was increased. The loudest sounds were obtained at the lowest end of the tube, where they were sometimes quite musical; and by increasing the pressure at regular intervals, a periodic increase and raising of the sound was produced, which closely resembled the sound heard in the

neck, to which the French have given the name of "bruit-de-diable."

2. A pin being stuck transversely through the tube, a slight blowing was heard. A similar phenomenon more distinctly resulted from the use of a split goose-quill placed in the same way. A stronger blowing was produced by two threads across the diameter of the tube, especially when they were rather loose; and a still louder and shriller sound ensued when a knot of string was fastened to the threads.

3. The same tube being adapted to the stopcock of a water supply-pipe, through which the current could be let to pass with great force, it was found possible to imitate every variety of blowing, whizzing, and musical murmurs, by varying the pressure on, or obstruction in, the tube, and by altering the force of the current. When the current was strong, the least obstruction caused a murmur, but with weaker currents, greater obstructions became necessary for the same effect. An obstruction, which, with a weak current gave a blowing sound, produced with a stronger current a sound of a more whizzing character. Grating or rasping sounds were best obtained by the effect of a strong current on a knotted thread across the diameter of the tube. The musical or uniform sounds resulted from a moderately strong current through a considerable impediment; increasing the force of the current or the degree of obstruction, rendered them whizzing and imperfect; diminishing the current or the obstruction, converted them into a simple blowing. When a sound was of an appreciable pitch, its note was high in proportion to the force of the current and the amount of the obstruction,—a fine forcible stream producing the highest note. Sometimes, however, with a strong current, a loud trumpet-note would be set up, which was not altered in pitch, but only in force, by changing the strength of the current. This kind of note produced visible vibrations of the tube below the obstruction, and seemed to have relation to the length of the tube. In many instances these vibrations resembled closely the purring tremor and thrilling vibration sometimes felt in the region of the heart and large arteries. Musical sounds of a more variable character, like the cooing of a dove, the humming of an insect, or the whistling of wind, were produced with weak currents passing through a tube much obstructed. The pressure of a column of water only two or three inches high was sufficient to give acute whistling notes, which were sustained, although varying, even when the water that passed only fell in drops from the end of the tube.

* As long as any air remains in the tube, a loud crepitation accompanies the current. In most of these experiments a flexible ear-tube, without its cone, was used, as being more easily applied than the common stethoscope.

4. Bending the tube to an angle produced a murmur; but no sound resulted from any curve that did not infringe on the calibre of the tube. A circular constriction, by a thread drawn round the tube, caused a murmur, which was blowing or whizzing according to the strength of the current.

5. The current issuing from the end of a tube, or from the mouth of an India-rubber bottle, produced a blowing sound when it impinged directly on an opposite surface, such as the side of the recipient or the end of the stethoscope; but unless the current were very strong, this sound was not produced when the current played on the surface very obliquely.

6. When the tube, with a weak current, was pressed on at two points, the murmur was heard at the point where the pressure was greatest; and by increasing the pressure at one point, the sound was stopped at the other. When the current was strong, it was easy, by a pretty equal pressure, to cause a murmur at both points.

7. With a strong caoutchouc tube, two feet long, and one inch in internal diameter, the same results were observed, but in a more remarkable degree, in consequence of the increased size of the tube. When the current was strong, and the pressure on the tube considerable, sounds were produced loud enough to be heard without applying the stethoscope to the ear, and the vibrations of the tube below the obstructions were so strong that they threw the water in little jets from the outside of the tube.

8. In making the last experiment, the pressure of the water suddenly distended a portion of the tube into a globe about three inches in diameter, constituting a good representation of a circumscribed true aneurism. As long as the force of the current was sufficient to keep the walls of the dilated portion distended, no murmur was produced; but when these walls became flaccid, the passing current caused a kind of dull fremitus in them. Slight pressure on the dilatation or bending the tube to form an angle at the point, also sometimes occasioned a murmur.

9. A globular India-rubber bottle, three inches in diameter, being adapted to an aperture in the side of a tube, so as to form an elastic sac communicating with it, and the air being expelled, the current of water was directed through the tube. The same was done with a smaller tube, and a bottle one inch and a half in diameter. In some positions the current, in passing the lateral sac, occasioned a slight whizzing; but in others, as when the tube was straight, there was no sound. A sudden increase of current, or the removal of pressure from the sac,

caused a whizzing, by the entry of water into the sac. Independently of the current, sudden forcible pressure on the sac occasioned a whizzing with the expulsion of the fluid; and a similar whizzing attended its rapid reflux into the sac on the removal of the pressure.

10. Some of the preceding experiments being repeated with water made slightly glutinous with size, it was found that the various sounds were not quite so readily produced as with plain water, and required a greater force of current.

From all these results (1, 2, 3, 4, 5, 6, &c.) it is sufficiently plain that a certain resistance or impediment to a liquid current is the essential physical cause of all murmurs produced by the motion of fluids in elastic tubes. That any condition of the walls of the tube beyond the obstructing point is not, as it has been supposed, essential to the production of these sounds, is proved by the fact, that they may be produced by an obstruction at the *terminal orifice* of the tube, or at the *mouth* of a gum-elastic bottle, where there is *no tube or wall beyond* to cause them (1, 5); and usually this is the situation where they can be produced best, because here the current has acquired its greatest momentum, and finds a freer passage beyond the obstructed point. The more flaccid state of the portion of a tube beyond an obstruction, is a necessary effect of the impediment caused by that obstruction to the passage of water. It is therefore a necessary concomitant of the obstruction, but it is not the *cause of the sound*. When, however, the sound occasioned by the obstruction is strong, its vibrations may be communicated to the whole contents and walls of the tube beyond (3, 7,) which will then vibrate in system with it, and be capable of modifying its note; just as the tube of a reed instrument *affects* the note which is *generated exclusively in the reed*. On the other hand, when the sound is weak and varying, the condition of the tube or walls beyond it will not affect it. In short, the laws of the production of sound by liquids, so closely resemble those which regulate the same phenomena in air, that it is unnecessary to enter into further detail respecting them. It may be necessary to advert to an objection to this view, that a murmur is sometimes caused where there is no impediment to the course of a liquid, as when it passes suddenly from a small into a large tube or into a sac. In the first place, it is not quite correct to assume that in this case there is no impediment; for the liquid in the large tube or sac having less velocity than that in the small one, must itself be an impediment. But besides this, the course of the small swift current becomes changed by spreading into

the larger channel, and instead of running smoothly parallel to the tube, now strikes its walls at an angle, causing a series of impulses and resistances which, if forcible and rapid enough, constitute the vibrations of sound. It is in the same way that a current produces a sound by impinging against an opposed surface (5.) It may be, observed, however, that these indirect kinds of impediment to a moving current, are not so constantly attended with the production of sound, as the direct obstacle presented by a narrowing of, or projection into, the calibre of the tube.

Experiments on the production of Murmurs in the Living Body.

11. About two inches length of the common carotid artery of a young donkey was laid bare. Different degrees of pressure, either by the stethoscope, or by a probe pushed under the artery, occasioned a variety of murmurs, blowing, sawing, filing, and musical or cooing, at each pulse. When the stethoscope was merely placed in contact without pressure, no murmur was heard, but only a simple impulse and sound, which was distinct only when the heart acted strongly.

12. The artery was scratched for a few seconds with the point of a scalpel; it gradually became sensibly smaller for the length of half an inch about that point. A strong solution of salt being applied, the contraction increased; but it was still of a gradual and tapering kind, and the stethoscope could not detect any murmur in it; very slight pressure was enough to cause a whizzing. The pulse at this contracted portion was felt to be much harder and sharper than above or below it.

13. A small incision being made into the artery, a jet of blood issued, and a whizzing, sometimes continuous like the bruit-de-diable, sometimes only in pulses, was heard beyond the orifice, but no sound on that side of the orifice nearest the heart; the sound being, as usual, carried in the direction of the current. The incision being made larger, the blood spouted out with whizzing to the distance of more than six feet, and the animal died in the course of ten minutes. After this last incision the beats of the heart were frequent, short, and pretty loud, but without a second sound, and without any murmur to the last. They continued for nearly two minutes after the respiration and consciousness had ceased, becoming gradually slower.

14. The Committee repeated the observation that has often been made before, that a murmur can easily be produced by pressure on the subclavian, carotid, or femoral artery of the human subject. This murmur is generally of a grating or

filing character, and is prolonged in proportion to the degree of pressure.

15. Whilst making the observations on the carotid, they found that a continuous murmur of very remarkable and variable characters could be produced by pressure on the jugular veins. The most common sound thus produced was like the humming of a gnat or fly, but occasionally it resembled the whistling of wind, the singing of a kettle, the cooing of a dove, and sometimes it was perfectly the remittent whirring noise, which the French have called the bruit-de-diable. Dr. Ogier Ward, of Birmingham, had previously come to the conclusion that this sound is produced in the jugular veins; and the observations of the Committee confirm this inference; but they do not agree with this physician in the opinion which he adopts from MM. Andral and Bouillaud, that the presence of these sounds always denotes a chlorotic state of the system, in which steel is indicated, or that they are essentially morbid symptoms at all. They may be produced in the healthiest subjects by moderate pressure applied to the lower part of the jugular veins, and are then found to be modified by various circumstances, which can only affect the venous current. Thus, they may be arrested or diminished by pressure on the vein above, by the horizontal posture, or hanging down the head, and by forced efforts to expire with the glottis closed. They may be restored in increased degree by suddenly desisting from any of these acts or circumstances. The occasional pulsatory or remittent character of these sounds seems to depend on the momentary increase of pressure caused by each pulse of the neighbouring artery; and when, as it sometimes happens, these pulses are attended with a whizzing, this is in a measure incorporated with the venous sound, and increases its periodic swell. The size and downward current of the jugular vein peculiarly adapt it for the production of sound, but it is probable that sounds may be produced by pressure on other veins, when circumstances accelerate the current within them. The Committee have succeeded in detecting an obscure murmur in some of the large superficial veins in the arm and thigh. It is to be distinguished from muscular sound, which it resembles, by its being heard only when the small end of the stethoscope is applied on a vein, and by its being stopped by pressure on that vein. A louder continuous sound is sometimes heard at each side of the upper part of the sternum, which, from its resemblance to these venous sounds, and from its being stopped by forcible expiration, may be supposed to have its seat in the large venous trunks underneath.

Although it appears from these facts that the venous sounds are not necessarily signs of disease, yet the circumstance proved by the Committee (10), that water is thrown into sonorous vibrations more readily than a liquid of a more glutinous character, renders it probable that these, and other sounds depending on the motion of liquids in the apparatus of the circulation, may be more easily produced where the blood is thin and deficient in quantity; and under these circumstances they may occur in the neck from the mere pressure of the muscles on the jugular veins.

The Committee had planned several experiments for the further elucidation of the second part of the inquiry, namely, *by what changes, functional and structural, does the apparatus of the circulation develop the physical causes of abnormal murmurs and sounds, in various instances in which they are known to occur?* Having failed in obtaining animals in time for this Report, the Committee propose to resume at a future time this part of the inquiry, so important for the elucidation of several obscure points in pathology, diagnosis, and practice; and to report the result of their labours at the next meeting, if the Association should think fit to reappoint them for that purpose*.

(Signed)

C. J. B. WILLIAMS, M.D. F.R.S.

ROBERT B. TODD, M.D.

Professor of Physiology, and General and Morbid Anatomy, King's College, London.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Nov. 28, 1837.

THE PRESIDENT IN THE CHAIR.

Removal of the Clavicle, with a Tumor situated in that bone. By BENJAMIN TRAVERS, F.R.S., Senior Surgeon to St. Thomas's Hospital.

THE patient, in this case, was a young gentleman, æt. 10, a native of the East Indies, but resident for the last five years in England. In the summer of 1836, a swelling, of the size of a hedge-nut, was observed in the centre of the left clavicle, which was attributed to a fall he had had ten days previously, and treated accordingly. At about two months after this discovery the author was consulted, when the swelling had attained the size of a pigeon's egg, was elastic, and painful when compressed. Various means were

had recourse to with the view of dispersing the tumor, but without avail, as by May, in the present year, its base, from the scapular extremity, occupied 3-4ths of the bone. About 2-3ds of its bulk were supraclavicular, so that in the erect posture it was seen far behind. It being determined to remove the bone with the tumor, the operation was performed on the 6th of June, twelve months after the commencement of the disease. The operation was effected without difficulty, and no considerable blood-vessels were injured. The entire clavicle was removed, with the exception of a small portion of its sternal extremity. At the date of the present narrative (Oct. 1837) the wound had been very completely cicatrized; there was no falling forward of the shoulder, nor any restriction of the motions of the arm: indeed, such facility does the patient enjoy in this respect, that one of his amusements is rowing a boat upon the Thames. There is a production of bone from the truncated extremity of the clavicle, extending at least two inches, and terminating beneath the centre of the cicatrix. A section of the tumor, in its longest diameter, presented an arrangement of cells filled with a dark solid coagula of blood.

The author conceives that there can be no reasonable doubt of two points, viz. that the tumor began in the cellular structure, and that it was the result, direct or indirect, of the fall. The explanation offered by the author is, that a medullary extravasation had taken place from the concussion attending the fall, or from the fracture within the periosteum, in either of which cases the effused blood which, in a perfect solution of continuity, would have been absorbed, acted as a foreign body; and by effectually stopping the osseous secretion and starving the bone, became the instrument of the absorbing process. He is induced, by the phenomena of such cases as the present, to entertain an opinion, that many anomalous fixed tumors on record arise from changes within the medullary canal of the bones, and are exasperated into intractableness by their confined situation. The paper concludes with a categorical summary of the diseases of bone, which the author's observation and the records of surgery enable him to verify.

ST. BARTHOLOMEW'S HOSPITAL.

Tuliocotian Operation.

SARAH JACKSON, æt. 20, a native of Hertford, came up to St. Bartholomew's Hospital, in the beginning of last August, to

* The Committee was reappointed, and £25 placed at their disposal for the further prosecution of these researches.

undergo an operation for the reparation of her nose, which had been destroyed three years previously, by lupus. The disease commenced when she was a child, eight years old, on the right cheek, and gradually extending its ravages to the integuments of the alæ and septum of the nose, destroyed the cartilages of the apertures, and removed the whole of the integument as high as the triangular portion, which it left subcutaneous. A small part at the anterior and posterior part of the fleshy columna still remained. After a time, the left side of the face became similarly involved, and medical aid was unable to arrest the progress of the disease for a period of eight years. The face at this time presented an irregular rugous appearance, much thickened from a deposit of lymph, with patches of bright-red vessels ramifying in the skin, and had an unhealthy aspect, although quite free from any appearance of the disease itself. She was admitted into the hospital, under the care of Mr. Stanley, who, after a careful examination, fearful of the operation again lighting up the original disease, refused to subject the patient to the liability of its return.

In this conclusion he was somewhat strengthened by Professor Dieffenbach, of Berlin, who visited the institution about this time. He was of opinion, that although it was an unfavourable case, there were still sufficient grounds to warrant the performance of an operation. Personal appearance being an important consideration with the young woman, she was importunate in her solicitations to take advantage of the opportunity surgical means offered; and after being duly informed by Mr. Skey of the liability of failure (to whose care she had been previously assigned), the operation was determined on, and performed on Saturday, the 21st of October.

The first step consisted in paring off the skin on both sides the alæ, over a surface of about one-third of an inch wide; to which treatment also the anterior and posterior part of the columna nasi were subjected. A perpendicular incision was then made down the bridge of the nose, commencing a little above the junction of the frontal with the nasal bones, and the sides were reflected sufficiently to admit of the insertion of the stalk of the flap brought down from the forehead. A low state of the forehead rendered it necessary to divide the flap of integument obliquely; the direction of it, therefore, was upwards, outwards, and to the right side. It was of a crucial shape, consisting of three portions situated at right angles

to each other: a perpendicular portion, or tongue, from half an inch to three quarters of an inch in diameter, to be applied to the septum, and two lateral ones, of rather larger dimensions, to be adapted to either alæ. The meeting of these formed the prominence of the nose. The tongue, or perpendicular portion, advanced close upon the hair; and the transverse ones extended from the upper part of the eyebrow below, to the hair also above. A thin stalk, of an inch and a quarter long, and a quarter of an inch broad, was then carried down to meet the incision made along the dorsum of the nose. A little smart bleeding followed, and occasioned a delay of about a quarter of an hour. As soon as this was repressed, the stalk was twisted upon itself towards the right side, introduced between the two reflected portions on the dorsum of the nose, and kept in its situation by ligatures applied at proper intervals. The same method was also employed to confine in their proper situation the alar and columellar portions.

At eight o'clock the same evening the transplanted piece of integument was quite warm, but rather pale. She was conscious of its being touched, and strange to say, referred it, not to that part of the forehead from whence it was reflected, but to the very identical spot on the nose on which it was fixed. The ligatures were removed on the third day. The whole of it had united, except a small piece just at the meeting of the left alar portion with the cheek, which afterwards filled up by granulation, and the junction of that part going to form the septum with the upper lip. No attempt has been made again to approximate this; it is just sufficiently pendulous to appear natural, and no separation is observable without looking carefully underneath. The only artificial means resorted to have been the introduction of some flue of dry lint up either nostril.

In a month after the operation was performed the twisted part of the stalk was divided, and a small elliptical piece removed, to take away the projection it produced. It is remarkable how much the new part has contracted; what appeared at first a superabundant bulging mass is now converted into an aquiline organ of ordinary dimensions, and, as far as one can judge, corresponds as near as possible with what would have been the shape of the healthy one.

The patient is still in Sitwell's ward of St. Bartholomew's Hospital.

(a.) This boy was thrown down and kicked by a horse. When admitted, there was a considerable swelling in the situation of the right pectoral muscle and axilla, which had a fluctuating feel. No pulse could be perceived in the right humeral or radial arteries, and the forearm felt cold. On the following day the swelling was not so prominent, but appeared more diffused, and occupied the back, near the posterior boundary of the axilla. The swelling and discoloration, which were clearly caused by extravasated blood, are now disappearing; but the pulse, which has always been distinctly felt in the left arm, is not yet (Nov. 27th) perceptible in the right. Whether the absence of the pulse on the injured side was owing to the pressure on the main artery, caused by the large quantity of extravasated blood, or to obstruction consequent upon some lesion of the vessel itself, or whether any irregularity existed before the accident, could not be clearly made out. The first supposition is improbable, since, now that the

tumefaction is almost entirely subsided, no pulsation in the principal arteries of the limb can be detected.

CASE OF UTERINE HEMORRHAGE
CURED BY ERGOT OF RYE.

A WOMAN, aged 24, of very weak constitution, was admitted into St. Thomas's ward, at the hospital of La Pitié, under the care of M. Piorry, on the 21st of July, 1837. After having been in a sickly state during the whole period of pregnancy, she had been brought to bed, a month before her admission, of a fine child, which was her first. The delivery was not very laborious for a first case, and was terminated by the efforts of nature alone. The catamenia have always been regular, and she has never had any uterine affection. Ever since her delivery she has continually lost blood from the genitals, and these floodings have gone on increasing, till the patient determined to enter the hospital. The blood discharged is generally fluid, but is sometimes mixed with black clots.

The general state of the patient, at the time of admission, was satisfactory, with the exception of the pulse, which was 110.

On placing the hand upon the hypogastric region, there was nothing irregular, excepting that the uterus seemed rather larger than it ought to be a month after parturition.

On percussion, there was resonance and elasticity of the abdomen, and a dull sound followed stronger percussion in the situation of the uterus. On examination *per vaginam*, it was found that the cervix of the uterus was dilated and gaping, so as to allow of the introduction of the first phalanx of the fore finger. The cavity of the cervix was partly occupied by a tumor of the size of a hazel-nut, and of irregular surface, which projected into the vagina. On tracing the tumor with the finger into the interior of the uterine cavity, it was easy to perceive that its size increased in proportion as the finger advanced farther. It could be circumscribed with the finger, so as to ascertain that it adhered neither to the neck nor to the most sloping part of the uterus.

Diagnosis.—A foreign body in the uterus; either a polypus, a portion of placenta, or organized clots of blood.

Prescriptions.—Twenty-four grains of ergot of rye, in two doses; emollient injections; the use of the bidet; barley water; a basin of soup.

July 22.—The patient has had shivering fits followed by heat, and colic during the night. On examination, it was found that no change had taken place with respect to the tumor: the neck of the

uterus and the external parts were extremely flaccid. Forty-eight grains of the ergot were prescribed, and quarter diet; the rest as on the preceding day.

23d.—No shivering. After the administration of the last dose of the ergot, the colic returned with more violence than on the preceding day. On examination, it was found that a larger portion of the tumor projected through the os tincæ; so that it appeared that an attempt at expulsion was beginning. By the help of the speculum, the tumor was seen to be greyish. A drachm of the ergot was prescribed; the rest as on the preceding day.

24th.—The uterine hæmorrhage and the colic continue; the os tincæ is not so open as yesterday; no other change: same prescriptions.

25th.—The patient is cold; the pulse small; the tongue white. The hæmorrhage has ceased: instead of which there is a white discharge, which is sanious, thick, and fœtid. A drachm of the ergot, the bidet, and emollient injections, were prescribed; with two basins of soup as the sole nourishment.

26th.—The tumor is larger, and projects more than it did yesterday. Prescriptions: a drachm of the ergot, a vapour bath, emollient injections, and quarter diet.

29th.—The patient is weak; her face has a worn-out look; the leucorrhœa continues, but is less than on the preceding days. Prescriptions: forty eight grains of the ergot, with four grains of subcarbonate of iron, and three-quarters diet.

30th.—A substance like an organized clot of blood has come away from the neck of the uterus; it is of the size of a large walnut, soft, and easily torn. Prescriptions: a drachm of the ergot; four grains of subcarbonate of iron; a vapour bath; and quarter diet.

31st.—The patient has suffered from severe colic; after which another substance, like the one of yesterday, was again expelled. Prescriptions: a drachm and a half of ergot; the rest as yesterday.

August 1st.—The colic continues as severely as before; nothing has been expelled from the uterus; the cervix is rather contracted; the patient has no discharge, either red or white, and, with the exception of the colic, does not suffer at all. Prescriptions: a drachm of the ergot, and four grains of subcarbonate of iron.

2d.—The colic has been accompanied by shooting pains in the loins, which the patient compares to those which she feels before the appearance of the catamenia. The os tincæ has completely contracted, so that the introduction of the fore-finger into the interior of the uterus is now impossible. Every thing combines to show that the uterus is entirely freed from the

foreign body which it contained. The general state of the patient is satisfactory; her physiognomy has improved; her complexion is returning; there is no discharge, except a slight leucorrhœa. Prescriptions: the use of the bidet; three-quarters diet.

3d to 8th.—The state of the patient is becoming more and more satisfactory; in fact, she has no pain. Prescriptions: the use of the bidet; twelve grains of carbonate of iron; half diet.

10th.—The patient requests to be dismissed, although the premonitory symptoms of the catamenia seem to be present. The leucorrhœa has entirely ceased; her general state is good. Cured.—*Gazette des Hôpitaux*.

INDECENT EXHIBITION IN CHARTER-HOUSE SQUARE.

To the Editor of the Medical Gazette.

SIR,

My attention was directed to an article in the MEDICAL GAZETTE of Saturday week last, on the subject of the offensive exhibition in Charter-House Square, to which you have referred. I am happy to find that an honourable medical tribunal denounces this system of publication, which, as regards the public, is highly indelicate, and is in no less degree offensive to the common and well-understood proprieties of medical society. When we reflect on the daily routine of medical practice, entailing as it does a necessary familiarity with scenes and circumstances often offensive to the natural and true English delicacy of either sex, we cannot but commend the good taste which, notwithstanding their familiarity with such scenes, enables our professional men to maintain the exterior of a natural refinement, and which rarely or never oversteps the modesty and decency of cultivated society.

Here and there we find a contrary example; and we have one before us. The individual in question has received abundant evidence, that his mode of publication is most objectionable and offensive. He has been told that it has too frequently raised a blush on the cheek of modest and respectable inhabitants, while the bold and unabashed vulgarity of the exhibition attracts the attention, and elicits the comments, of the numerous youthful members of resident families.

We are told that public law has overlooked an evil of this description, and that, through its instrumentality, we can obtain no redress. But surely the proprieties

of social life are not to be outraged with impunity, and I earnestly hope that you will not withhold from us your aid in the endeavour to remove an evil that has received the unanimous denunciation of every householder around.

It is stated that our complaint is founded on personal dislike to an individual; that a conspiracy exists among, at least, the medical inhabitants of the Square, having for its real object the ruin of the rising institution. Certainly, the conduct of the individual alluded to is not, in this instance, such as to claim much general respect,—and most assuredly have we a sufficient amount of provocation, without the necessity of inferring hostility to any object, having the *real* interests of the poor at heart, and for which idea of hostility there is not, as far as I know, the slightest pretence. At all events, whatever be the sentiments of the individual under whose fostering hand the institution has obtained its unenviable notoriety, surely its Governors at large would never willingly connive at so gross a breach of common decency. They might possibly be induced to consider, whether their ill-bestowed philanthropy may not be directed into some more profitable channel, on learning that the diseases, for the cure of which “the Infirmary” was instituted, are, as I am informed, the subject of daily treatment in every hospital in London.

I remain, sir,

Your most obedient servant,

AN INHABITANT OF

CHARTER-HOUSE SQUARE.

Nov. 27, 1837.

To the Editor of the Medical Gazette.

SIR,

THE observations in a late number of your journal, on the indecent mode of advertising resorted to by a surgeon in Charter-house Square, entitle you to the warmest thanks of the inhabitants in this neighbourhood. I am sorry to say that, even so recently as Friday last, there was an advertisement in the *Times*, with “Surgeon to the Infirmary for Diseases of the Rectum, 38, Charter-house Square,” appended to the name.

Trusting that the observations which you have made will abate the particular nuisance referred to by you, and above all prevent the repetition of such advertisements from regular professional men, I am, sir,

Your obedient servant,

A SURGEON.

Charter-house Square,
Nov. 13, 1837.

viction.—A single Fact proved by Circum-

stantial Evidence not sufficient.—Chain of

Circumstantial Evidence.—Cumulative Na-

ture of Circumstantial Evidence illustrated

by the Case of Capt. Donnellan.

Evidence the source of all human knowledge.

—Evidence is the source of all human knowledge, and the guide of all human action. All that we know of natural philosophy, of natural history, of moral and political science, of medicine, we derive from evidence—that is, from the collection, verification, and comparison of facts: classes of facts observed by ourselves or others, either as they arise spontaneously, or after the bodies in question have been put for the purpose into a certain situation.

Evidence a means to an end.—Evidence

being thus merely a means to an end, and being conducive to a great variety of ends, we are now to consider it with a special relation to legal objects: and more especially we are to consider medical evidence as it is applicable to a judicial purpose.

Legal evidence.—Legal evidence is a general name given to any fact which is submitted to the cognizance of the judges of the law. In the English courts, the tribunal of justice consists of the jury and the judge. Legal evidence is the name given to any fact which is submitted to the cognizance of the jury and the judge—submitted with the view that it should produce in their minds a conviction of the existence of some other fact; a conviction to be followed, on their parts, by a legal decision.

Medical evidence.—Medical evidence is a general name given to a class of facts the knowledge of which is derived from the science of medicine and its collateral branches; and which, in like manner, is presented to the jury and the judge, in order that it may form the basis of a legal decision.

Legal decision founded on evidence.—The legal decision relative to a question of fact, in as far as it is just, entirely depends upon, and is governed by, the evidence.

If evidence of a sufficient degree of probative force to satisfy the jury and the judge, of a matter of fact which is necessary to be known, be wanting, the law, in that instance, fails of receiving its due execution and effect.

Consequence of fallacious evidence.—If the effect of the evidence actually presented to the jury and the judge be to produce in their minds a material and decisive deception—that is, the persuasion of the existence of some matter of fact which was not in existence—the consequence of such persuasion must necessarily be an unjust decision; and the ultimate effect of such fallacious evidence is precisely the same as the result which would be produced by the

failure, the want, or the deficiency of evidence.

Hence the extreme importance of guarding against the deception liable to be produced by fallacious evidence; and the necessity that you, who, as skilled witnesses, are to collect and state evidence in relation to numerous questions, some of them of the greatest delicacy, difficulty, and importance, which are ever presented to the judges of the law for their decision, should be able to form a correct judgment of the probative force of evidence, and should take the necessary securities that the evidence you deliver possess the highest attainable degree of probative force; that is, be in the highest attainable degree trust-worthy.

Probative force of evidence.—The properties which give to a mass of evidence its highest degree of probative force, or which constitute its perfect trust-worthiness, are two—correctness and completeness.

Correctness consists in the perfect conformity of the statement given in relation to a fact to the fact itself. In proportion as a statement fails of possessing this perfect conformity to the fact in relation to which it is delivered, in the same proportion will the mass of evidence fail of attaining the maximum of trustworthiness; and precisely in the same proportion will be the danger of deception, and of consequent misdecision on the part of the judges.

Completeness consists in the perfection with which the statement includes all the circumstances that are essential to the justice of the decision.

How incorrectness or incompleteness produces false judgment.—If the aggregate mass of evidence be deficient in completeness, its correctness, instead of being a cause of trustworthiness, may be the cause of the most entire delusion; instead of being a security against deception and consequent misdecision, deception and misdecision may be the inevitable results of it.

Evidence may be incomplete as respects a single article of it—such as the testimony of a single individual; or as respects the whole body of it, considered in the aggregate. In the latter case, the body may be rendered incomplete either by incompleteness on the part of any one or more of the articles of which it is composed, or by the entire absence of any one or more of the articles which ought to have entered into the composition of it.

Incompleteness and incorrectness tend to produce deception, by producing partiality. Evidence has for its object, rectitude of decision; but wrong decision necessarily results either from incorrectness or incompleteness. One object, then,

essential to the attainment of the ends of justice, is the prevention of deception, and consequent false judgment.

False judgment, what.—Judgment regarded as false, is so regarded with relation to some other judgment taken as a standard. This standard can never be any other than the judgment of the individual by whom the term deception is employed.

A mass of evidence is produced, affirmative of a fact, tending to satisfy the tribunal of the reality of the existence of this fact. This evidence produces the wished-for persuasion in the minds of the judges. In my opinion, the evidence in this instance is deceptive, and consequently misdecision has taken place. In other words, of the body of evidence in this instance presented to the judges, the probative force is not, in my judgment, great enough to warrant the conclusion which they have drawn from it—namely, a conclusion expressive of their belief in the existence of the fact in question.

Degrees of probative force.—The very terms in which this my opinion is expressed, assume that evidence delivered in relation to a matter of fact is susceptible of degrees in point of quantity. In my own opinion, in the present case, the quantity of this quality was not sufficient to produce the effect which it did produce on the minds of the judges. This being the case, it is impossible for me not to regard the judges as having, in this instance, been deceived.

Standard degree.—The quantity of probative force incident to a body of evidence, is, then, susceptible of degrees. Of these degrees let us, for the purpose of discourse, form a nominal standard of comparison. Suppose a witness an individual taken by lot, and unknown to the tribunal, deposes that a certain matter of fact, under the circumstances stated by him, presented itself to the cognizance of his senses: Suppose that there be no counter-evidence: the probative force possessed by an article of evidence of this description may be called the ordinary degree of probative force.

It is precisely by evidence of this description that belief is commonly produced. In the great majority of cases, the belief thus produced is right judgment, not deception.

It is, however, notorious, that of the belief thus produced, deception is occasionally the consequence.

But in another case in which the quantity of probative force is, to a certain degree, greater than in the one first mentioned, deception is not so frequently the consequence.

Here, then, we have an assumed no-

minimal standard of comparison for the probative force of evidence. A mass that comes up to this standard, but does not rise above it, is what is meant by an ordinary body of evidence; a mass that rises above it may be termed a body of super-ordinary or superior evidence; a mass that falls short of it may be termed a body of infra-ordinary or inferior evidence.

The greater the quantity of probative force in the mass of evidence produced on one side, deduction made of that produced on the other, the more certain in the eyes of a by-stander will be its effects on the minds of the judges, and the greater in the minds of the judges will be the ease with which their judgment of belief, pronounced on the strength of it, will be accomplished.

Qualities by which the probative force of evidence may be raised above or below the standard.—A quantity of probative force being thus marked out for a standard, what are the qualities by which that quantity is capable of receiving increase and decrease?

1. One source of increase is derived from the quality of the supposed percipient witness. In the case here supposed, the deponent was taken from the middle rank, in respect of qualities intellectual and moral. But, suppose that the station of the witness, whether constituted by education, opulence, rank, power, profession, official function, or by any combination of these circumstances, is, by general experience, found to render a man less apt, on the kind of occasion in question, to deliver a statement in any respect incorrect or incomplete than a man of a different condition; here, then, in the condition of life of the witness, we see one source from which the probative force of an article of evidence may receive increase.

On this ground stands whatever superior degree of credence is commonly given to official evidence in general, or to the testimony of persons invested with judicial offices in particular.

2. Another source of increase is that derived from the number of witnesses. Here the mode of increase being of the utmost simplicity, the degree of it is susceptible of measurement with mathematical exactness.

3. To the number of witnesses, and a more than ordinary degree of presumable trustworthiness on their part, may be added a third source of increase, capable of augmentation to an indefinite amount,—the sort of evidence termed real; evidence derived from some object or objects belonging to the class of things, in contradistinction to the class of persons.

On the other hand, the circumstances which tend to diminish the probative

force of evidence are any manifest imperfection in the intellectual faculties of the deposing witness; any imperfection in his moral qualities, more especially any circumstances which indicate that he is under the influence of sinister interest; the word interest being understood here in its largest and most comprehensive sense, as including not only self-regarding interest, but the interest caused by sympathy or antipathy towards other persons, whether taken as individuals or as classes. Such motives as tend to dispose a witness to yield to the force of interest acting in a sinister direction, are referable to the head of improbity.

Perjury and bias.—When the deposition of a witness is incorrect or incomplete, he is either conscious of such incorrectness and incompleteness, or he is unconscious of it. If he be conscious of it, his testimony is the result of mendacity; which mendacity, if the ceremony of an oath have been applied to it, constitutes perjury; if he be unconscious of it, the imperfection is said to result from *bias*.

Persuasion, then, exists in different degrees of strength. The strength of persuasion on the part of the judges, will, if the testimony of the witness be believed, be as the strength of persuasion expressed by the witness.

The strength of persuasion expressed by the witness will, if clear of wilful falsehood, be exactly the same in degree with the strength of persuasion actually felt by him at the time.

Expression of strength of persuasion.—Suppose, on comparing together the testimony delivered by three witnesses, it appears to the judges that these witnesses all joined in regarding the existence of a certain fact as more probable than the non-existence of it, whereas, in truth, the force of the persuasion of the witnesses lay on the opposite side, here an instance of misdecision will have taken place on the part of the judges, and no worse could have happened had the testimony of none of these witnesses been forthcoming; or had all the witnesses, after joining in a tale of wilful falsehood, obtained credence for it, as if it had been true. Hence the paramount importance of a correct mode of expressing degrees of persuasion.

The language of common parlance is, in this respect, deplorably defective:—I think; I know; I believe. The event happened so and so. I think it happened so and so. I believe it happened so and so. Here the gradation ends.

In the language of the law little better is found. The terms by which the degrees of probative force are expressed in English law are:—1. Positive proof. 2. Violent presumption. 3. Probable pre-

snupition. 4. Light or rash presumption. By positive proof is designated direct evidence; below it stands circumstantial evidence. Violent presumption, it is said, is many times equal to full proof; probable presumption hath also its due weight; while light or rash presumption has no weight or validity at all.

Bentham's scale.—In order to afford the means of expressing degrees of persuasion, or of probative force, with greater exactness, Mr. Bentham proposes the formation of a scale consisting of two parts; the degrees of positive persuasion, or the persuasion affirming the existence of a fact, to constitute one part of the scale, the positive part.

The degrees of negative proof or persuasion, denying the existence of the same fact, to constitute the other part of the scale, the negative part.

Each part is divided into the same number of degrees, suppose ten. At the bottom of each part of the scale stands 0, by which is denoted the non-existence of any degree of persuasion on either side, the state the mind is in when the affirmative and the negative of the fact in question appear as probable the one as the other.

Three persons appear as witnesses. Each expresses his degree of persuasion by this scale. Suppose that persuasion to be on the affirmative side; each indicates the same number, the number one.

In these three instances the force of persuasion is at the least amount at which it can stand on either side.

Suppose, in relation to this same fact, two other witnesses appear, who state their force of persuasion to be at its maximum, represented by the number 10.

Of these two witnesses, the persuasion may be on the same side as that of the three witnesses, or it may be on the opposite side.

Suppose it on the opposite side, the negative. Out of 30 degrees of persuasion which the three witnesses might have had, they have but 3; while of the 20, the utmost number which the two were capable of having between them, they have the whole.

According to the ordinary mode of expressing degrees of persuasion, these differences are unascertainable; they cannot be presented to the minds of the judges; the judges can, therefore, do no otherwise than decide according to the number of witnesses; consequently their decision will be, that the fact does exist.

By the scale now described these differences are ascertainable, and are capable of being presented to the minds of the judges. Suppose, accordingly, the judges

to be guided in their decision by the force of persuasion on the part of the witnesses on both sides taken together; the decision will be that the fact does not exist.

Here, then, it is manifest that a directly opposite decision will be formed by the judges, according as the witnesses have or have not at their command the means of expressing clearly and accurately the degrees of persuasion produced upon their minds by the facts of which they have been cognizant. Where men have been in earnest to express degrees of persuasion, they have found no difficulty in inventing a language capable of doing so with the nicest precision, as is manifest in the case of wagers, and is hourly exemplified in the language of betting. Were benevolence as general and powerful a spring of human action as the love of pleasure or of profit—had men taken the same interest in the administration of justice as they have in providing for their amusement or their gain—the courts of law would not, in this stage of civilization, be so utterly destitute of every form of expression by which the witness can communicate to the judge a perception of the degree of force with which the persuasion to which he testifies may exist.

Direct and circumstantial evidence.—Evidence is either direct or circumstantial. It is important that you should have a clear conception of the difference in the nature of these two species of evidence, and of their different degrees of probative force.

Direct evidence is evidence which relates immediately to a principal fact; circumstantial evidence is evidence which does not relate immediately to a principal fact, but to some other fact evidentiary of a principal fact.

Direct evidence is derived immediately from sense, and does not depend on inference; circumstantial evidence is never derived immediately from sense, and is always the result of inference. I see a man with a sharp weapon inflict a wound upon another man, of which I also see that the latter instantly dies. In this case I am what, in the language of jurisprudence, is termed a percipient witness; and in bearing testimony to this fact I give what is called direct evidence. That a mortal wound was inflicted by a particular individual, with a particular weapon, is in this case not a matter of inference, it is a matter of sense; and the fact being attested by a percipient witness, it is said to be proved by direct evidence.

But it often happens that the principal fact, the fact sought, has been perceived by no human eye—has fallen within the observation of no human being. In this case

it is left to be inferred from other facts, of the existence of which there is no question, and which are so connected with the principal fact, as to be evidentiary of its existence—evidentiary in such a degree as to prove its existence.

Evidentiary facts thus connected with the principal fact, constitute what, in the language of jurisprudence, is called *circumstantial evidence*. He, then, who gives direct evidence, avers, that at a specified time and place, the principal fact in question came within the cognizance of his senses; he who gives circumstantial evidence states the existence of some fact which induces the inference, which leads to the conclusion that, at the specified time and place, the principal fact did exist.

In every case of circumstantial evidence, then, there are always at least two facts to be considered: 1. The fact to be proved; that is, the principal fact—the fact evidenced to. 2. The fact proving the evidentiary fact; the fact from the existence of which that of the principal fact is inferred.

Facts and inferences.—Direct evidence is a species of evidence hardly ever to be obtained. It is exceedingly rare that a principal fact is established by direct evidence alone, without any admixture of circumstantial evidence. Even in the case of evidence adduced by a percipient witness, by an individual who deposes that he saw the fact, still it is extremely rare that the belief of any matter of fact is produced, even in relation to an object of sight, without the judgment having been more or less at work in the production of it. The operation of sense is restricted to the simple perception; inference is the operation of the judgment.

You see a wound inflicted; you see that death immediately follows. Even in this case, all that is properly an object of sense is the infliction of the wound and the death. That the death is the consequence of the wound is a matter of inference; but in this case the sequent is so closely connected with the antecedent, that the evidence is as direct as can well be conceived. It is rare, indeed, that any evidence so direct as this is obtainable for a judicial purpose.

A man was found in his bed-room, at an inn, weltering in his blood; he was speechless, and died in a few minutes. The innkeeper was discovered in the room with a weapon in his hand, with which it was manifest that the wound had been inflicted. When discovered in this situation the innkeeper appeared confused and terrified, and betrayed in his manner all the signs of conscious guilt.

You must be careful not to mistake a case like this for a case of direct evidence. All the direct evidence here is, that a man is seen to die; that a wound is perceptible on his body; that another man is found in the room with a weapon in his hand; and that the deportment of this second man is of such and such a nature. If you had seen the innkeeper inflict with the weapon in his hand the wound upon his guest, and had actually witnessed the immediate death of the latter, then the murder would have been an object of sense, and you would have been able to give, according to the strict meaning of the term, direct evidence of the fact. But you saw no such thing. That the innkeeper was the murderer is an inference deduced from the evidentiary facts—the only facts of the case, namely, that he was found in the room, that he was armed with a weapon, and that his deportment on being discovered in this situation was such as in your conception is natural to a man detected in the commission of a great crime. This inference may be true, or it may be false. The evidentiary facts may be sufficient to warrant your conclusion, or they may be altogether fallacious. The guest may have inflicted the wound upon himself: the innkeeper having heard an unusual noise in the room, may have entered it to see what had happened; and the shock produced by so horrible a sight may have occasioned that appearance of confusion and alarm in his deportment which you falsely attribute to conscious guilt; or the wound may have been inflicted by some other person, who had made his escape unseen.

I shall have occasion again to advert to this case for another purpose; I mention it now merely to direct your attention to the importance of distinguishing between facts and inferences.

However completely a certain fact or event may be a matter of sense, it is impossible that any fact of a criminal nature can be established by direct evidence alone. In order to constitute a criminal act there must be intention—intention to bring about the obnoxious event; but no human being can judge of the intention of another but by an inference deduced from his action.

While it is thus scarcely possible to establish the existence of a principal fact, and not possible if this fact be of a criminal nature, purely by direct evidence, yet it is often established by circumstantial evidence alone, without the aid of any direct evidence whatever. Were it otherwise, it would be seldom possible to prove the commission of the most atrocious crimes, for the evil-doer takes care to

choose an opportunity for perpetrating his crime when he believes that no human eye is on him; and often no human eye is on him. But for circumstantial evidence, therefore, it would be extremely rare that the commission of the offence could be brought home to him.

Evidence, then, is direct in regard to every fact in which a deponent reports himself as having been a percipient witness—circumstantial in regard to every fact not thus a matter of sense, but the existence of which is matter of inference.

The truth of any legal decision, grounded on direct evidence, depends altogether upon the verity of the testimony. If, consciously or unconsciously, the facts stated to have been matters of sense are misrepresented, the decision will be erroneous.

The truth of any legal decision, grounded upon circumstantial evidence, does not depend upon the verity of the testimony, but upon the justness of the inference deduced from it—on the real connexion between the fact evidenced and the fact inferred. If the inference grounded on the testimony be a just inference, the decision grounded on that inference may be a just decision, though the testimony upon which it is based be false. A man is suspected of murder; he is interrogated on the subject of it by a judge. Suppose him guilty: he confesses the fact. There is here no demand for inference; the testimony amounts to a full confession; it operates purely in the character of direct evidence. He does not confess the fact; question upon question is pressed upon him; his replies are evasive; they contain, as is always the case under such circumstances, a mixture of truth and falsehood. The testimony now, that portion of it which is true, not being full enough to operate of itself with a conclusive force in the character of direct evidence, it is consulted, it is made to operate further in the character of circumstantial evidence. In this character it may be full enough to operate even conclusively; it may afford full satisfaction; it may generate a full persuasion, though in the character of direct evidence it may be altogether deficient.

In this case such parts of the testimony as are false may contribute to the support of the conclusion just as much as the facts that are true. Taking the narrative as a whole, if any falsehood be introduced into it, such falsehood will afford a strong evidence of delinquency. On examination of the details of the transaction, this or that particular falsehood may afford an inference establishing this or that particular truth. Thus an assertion representing this or that fact as existing at a certain time

and place, which did not exist at that time and place, or representing as not existing a fact which did exist, may afford a perfectly satisfactory inference as to the existence, or the non-existence of this or that particular fact.

A single fact proved by direct evidence sufficient to warrant conviction.—When a principal fact is an object of sense, and is proved by the direct testimony of a percipient witness, it is universally admitted that sufficient ground is afforded for the decision of the jury and the judge. Accordingly, under the law of England, whenever a single person, in the character of a deponent, declares that such a fact came under the cognizance of his senses, conviction follows as a matter of course, provided the jury and judge be satisfied that the senses of the witness were not deceived, and that his testimony is not false.

A single fact proved by circumstantial evidence not sufficient.—But this is by no means the case with circumstantial evidence. One fact, evidentiary of a principal fact, is rarely, if ever, sufficient to warrant conviction. One single circumstance may beget a suspicion of the fact; a second may render it probable; a third may render it highly probable; and a fourth may induce such a strong persuasion of it, that the thing may be considered as proved. Of two evidentiary facts, take one by itself, its probative force may be scarcely worth regarding—take both in conjunction, they may now afford a very considerable degree of probative force—add to them a third, the probability may be greatly raised—add still a fourth, a fifth, you will at length come to a point where the evidence can be no longer resisted. Circumstantial evidence is thus cumulative, and the completeness of the proof often depends on the number of independent facts which thus connect themselves with each other, and bear upon the point in question.

Chain of evidence.—And this constitutes what is termed a chain of evidence. A number of facts independent of, but closely connected with, each other—each taken by itself proving next to nothing—all taken together forming perhaps complete proof. Such is what is termed a chain of circumstantial evidence.

Cumulative nature of circumstantial evidence illustrated by the case of Captain Donnellan.—For the purpose of affording an illustration of the cumulative nature of circumstantial evidence, I recal your attention the celebrated case of Captain Donnellan, to which I adverted in the first lecture.

On March 30th, 1781, at the assizes at Warwick, Captain Donnellan was con-

victed of murder, committed by poisoning Sir Theodosius Boughton. This case may be taken as an example of an aggregate body of circumstantial evidence, approaching, perhaps, as nearly to completeness as the nature of circumstantial evidence admits; while the individual facts taken separately can be scarcely said to prove any thing.

In right of his wife, Captain Donnellan had an interest in the estates of Sir Theodosius Boughton. He formed the determination to take away, by some means or other, the life of this young man. To shut the door against suspicion, he began by propagating the notion that the state of the young man's health was desperate—that his death would certainly take place at no distant period—that his imprudence was continually heaping up causes upon causes. All this time he was only labouring under a trifling complaint, and was guilty of no imprudence manifest to any one about him.

The poison fixed upon by the murderer was distilled laurel water. It was in his statement relative to the effects of this poison on the human body, that Mr. John Hunter appeared to such disadvantage as a medical witness. To avoid the suspicious circumstance of the purchase of poison, Donnellan provided himself with a still, for the fabrication of it. He practised distillation frequently. The room in which he operated he kept locked up. The poison was now prepared; how was it to be administered?

The young man was taking medicine for a slight complaint under which he was suffering. The phials, as they came in, were usually placed by the invalid in an inner room, which he had been in the habit of locking up. He happened once to forget to take his medicine. "Why," says Donnellan, "don't you set it in your outer room, you would not then be so apt to forget it?" The fatal advice was followed. Soon afterwards a draught taken from the shelf of the outer room, marked "Purging draught for Sir Theodosius Boughton," was given to him by his mother, Lady Boughton. She observed to her son at the time she gave him the draught, that it smelt very strongly of bitter almonds. In two minutes after taking the contents of this phial, the young man was seized with violent symptoms, and in a few minutes more he expired.

Now in all this there is no direct evidence attaching guilt to Donnellan; and if the evidentiary facts are examined singly, how feeble are they—if viewed in the aggregate, how conclusive!

Donnellan practised distillation. As a proof of poisoning, to what did that

amount? Next to nothing. At that rate all distillers would be poisoners.

Not engaged in distillation—not engaged in any other occupation, with a view to profit—not engaged in chemistry in any other shape, still he practised distillation. To what did that amount? Something more perhaps, but still very little more. At that rate all the Lady Bountifuls in the country would be poisoners.

He distilled what there was reason to think was laurel water, a known poison—a substance not known to be used for any other purpose; the proof strengthens, but still it is very far from conclusive.

Thus much as to preparations, though there were others, which I pass over. Go on next to motives. The relation of the defendant to the deceased was such, that upon the death of the latter a large property was to devolve upon the former. Does it follow that, at the expense of so horrible a crime, he endeavoured to occasion such death? At that rate the most common of all causes of death would be parricide.

Now observe how the addition of another circumstance—how the addition of another link in the chain, affects all the preceding. In less than five minutes after the fatal draught had been swallowed by the young baronet, Donnellan came into the bed-chamber where the dying youth lay. On the trial, Lady Boughton deposed as follows:—

"On coming into the room, Capt. Donnellan asked me in what manner Sir Theodosius was taken. I told him. Then he asked me where the physic-bottle was? I shewed him the two draughts. He took up one of the bottles, and said, 'Is this it?' 'Yes,' said I. Then he took it up, poured some water out of the water-bottle, which was just by, into the phial, shook it, and then emptied it out into some dirty water, which was in a wash-hand basin. Observing this, I said, 'What are you at? You should not meddle with that bottle.' Upon that, he snatched up the other bottle, poured water into it, and shook it; then he put his finger to it, and tasted it. I said, 'What are you about? You ought not to meddle with those bottles.' Upon which he said, 'Oh! I did it to taste it.' The first bottle, however, he did not taste."

Now the circumstance that laurel-water was contained in either of these phials was a most material fact; it was a piece of real evidence of the last importance. Even the smell of laurel-water in either of the phials was an evidentiary fact of the greatest moment. Donnellan knew that the smell of laurel-water had been recognized in the draught taken by the deceased; he

saw that observation was directed to the remaining phials; conscious, apparently, of the importance of destroying this object of real evidence, he emptied the bottles of their contents, and rinsed them out.

I add two other links to the chain, of scarcely any strength when considered by themselves, but of considerable strength when connected with the preceding.

In about a quarter of an hour after leaving the bed-chamber of the deceased, Capt. Donnellan met the maid-servant in the passage. He said to her, "Sir Theodosius was out very late over nights a fishing; it was very silly of him since he had been taking such physic." And some days afterwards, he brought to this maid-servant a still which she deposed had been well washed, and which he desired her to put into the oven to dry it, that it might not rust; "but I said, if I put it in, then it would unsolder it, as it was made of tin."

Observe, now, how the probative force strengthens with the addition of every link to this instructive chain of evidence! How the subsequent facts shed light upon, and add importance to, the anterior events! The forewarning that the young man was to die; the distillation of one of the most potent poisons then known; the opportunity sought and procured of administering this poison; the recognition of this identical poison by its smell, when the draught was given by the mother to her son as a purging draught; the death of the young man in a few minutes after taking this draught; death attended with all the symptoms which this very poison is known to produce; the conduct of the suspected murderer in the bed-chamber; his anxiety to destroy the evidence of the existence of the poison in question, by throwing away the remaining portion of it, and destroying even its smell; his attempt to assign a false cause for the death of the deceased; his subsequent *cleaning* of the still; his wish to get it placed in a heated oven, that no suspicious smell might by possibility remain attached to it; and lastly the large property that would come into his possession on the death of the deceased. Take any of these circumstances by itself, how inconclusive! take each in connexion with the rest, and view the whole combined, forming together an aggregate body of evidence, how conclusive!

Such, then, is a chain of circumstantial evidence, composed of a number of independent but closely connected facts, all concurring to produce in the mind a persuasion of the existence of some other fact—a fact sought—a persuasion which may be said to be irresistible.

ON THE COMPOSITION AND ABSORPTION OF PUS.

BY M. BONNET,

Surgeon to the Hôtel-Dieu, at Lyons.

Examination of pus by re-agents.—Parts soluble in water of the ordinary temperature.—Parts soluble in boiling water.—Parts soluble in boiling alcohol.—Parts insoluble in cold water, boiling water, and alcohol.—Pus examined by the microscope.—Examination of pus by exposing test-papers to its vapour.—On the immediate principles always found in pus.

Pus is one of the products most commonly secreted in disease; and is one of those which, by the compression which they cause, the ulcerations which they produce, and the injurious principles which they supply when absorbed, give rise to the most numerous and serious symptoms. Nevertheless, in spite of the importance of its effects, it has been scarcely studied. We have but imperfect notions—

1st, As to the methods of ascertaining its composition;

2dly, As to the immediate principles always found in it;

3dly, The differences in the composition of its several varieties;

4thly, The changes which it undergoes when it is in contact with the air and putrefies;

5thly, The nature of the principles which it supplies when absorbed;

6thly, and lastly, We have no certain method of preventing its contact with the atmosphere, and its consequent putrefaction, after the opening of great abscesses of the joints and pleura.

I have endeavoured to supply these deficiencies, and shall set forth in this memoir the results at which I have arrived.

SECT. I.—On the Methods to be adopted to ascertain the Composition of Pus.

I have studied the composition of pus—1st, by re-agents; 2dly, by chemical analysis; 3dly, by microscopic analysis; 4thly, by exposing test papers to its vapour.

(a.) *Examination of pus by re-agents.*—The only immediate principle which can be recognised in pus by means of re-agents, is soluble albumen; for the precipitates caused by this substance mask every other one, or even hinder them from being produced, as one may convince oneself by the following experiments:—

1. Prepare a soluble albuminate of deutoxide of mercury according to Berze-

lius's method*; mix the serum of the blood with small quantities of the deutochloride of mercury, and then add rather more caustic potash than is required for the decomposition of the salt; you will obtain a transparent solution, and the deutoxide of mercury will form a soluble combination with the albumen. In this state the metallic salt can no longer be detected by the most delicate tests; for alkalies, hydriodates, and soluble hydrosulphates, which detect it so readily in aqueous solutions, produce neither precipitate nor change of colour when it is dissolved in combination with albumen. Reagents are equally powerless in detecting albuminates of lead, copper, and deutoxide of tin: it is incineration alone which enables us to recognise metallic oxides combined with albumen, whether the latter be derived from the white of egg, from blood, from pus, or from dropsical fluids.

2. I mixed soluble albumen with a few drops of hydrosulphate of ammonia. This salt, though I could recognise it with the greatest facility in watery solutions that were five times weaker, could no longer be detected by re-agents, when once mixed with albumen. The salts of lead, mercury, antimony, and deutoxide of tin, afforded only white precipitates, instead of the black, reddish, and yellow ones, which they so easily produce in the aqueous solution.

These experiments are conclusive; they make one readily believe, that if mineral substances, so easily recognised as the oxides of mercury, lead, or copper, and the hydrosulphate of ammonia, can no longer be discovered by tests when dissolved in albumen, or mixed with it, animal substances which, in general, have so few characteristic marks, will be much more difficult to detect, if they are masked by the same principle. Hence, we must not be surprised at the powerlessness of re-agents in leading us to the composition of pus and its varieties. Here, as well as in the study of all animal substances, and particularly of those containing albumen, re-agents are useless until they are brought to act upon immediate principles separated by solvents; in short, they cannot be used before we have had recourse to analysis.

Nevertheless, most investigators of animal chemistry multiply the use of re-agents, and fancy that they find the tints and the precipitates which are characteristic of certain morbid products, such as pus, tubercles, &c.; and even think they can distinguish the varieties of these products. They should abstain from making these attempts by a method whose barren-

ness I wish that I had been earlier acquainted with. If my reflections and experiments are unable to persuade them, I refer them to the tables of reactions published by Tiedemann and Gmelin, in their *Researches on Digestion*, as well as to all the examinations of animal substances made by re-agents alone; they will then be convinced how confused and incomplete are the results obtained by this method, and how necessary it is to adopt more precise ones.

(b.) *On the study of pus by chemical analysis.*—After I have examined the physical characters of the pus, and ascertained whether it is neutral or alkaline, I dilute it with water of the ordinary temperature, and place it upon a filter. The part which is soluble in this water passes but slowly, and only a portion of it goes through the filter; it is put aside after waiting eight or twelve hours. All that remains upon the filter is mixed with triple or quadruple its volume of water; and when all the albumen has been coagulated by continued boiling, I again filter, and thus obtain separately the part which is soluble in boiling water. The insoluble part is dried, powdered, and, after being several times exposed to the action of boiling alcohol, is, in its turn, separated by filtering. Thus the pus is divided into four parts; the first being soluble in water at its ordinary temperature; the second in boiling water; the third in boiling alcohol; and the fourth being insoluble in any of these menstua.

1. *Parts soluble in water of the ordinary temperature.*—This portion, which contains the same elements as the serum of the blood, is boiled until the albumen is coagulated. It is then placed on a filter. The coagulated albumen remains above, and the solution which passes through the filter is now mixed with the one obtained by boiling the pus in water.

2. *Parts soluble in boiling water.*—This portion is evaporated, and its extract is exposed to the action of boiling alcohol, which dissolves the alcoholic extract of meat, as well as the hydrochlorates of soda, potash, and ammonia. After employing the re-agents fitted to detect these salts, I crystallize them on a slip of glass, and examine them in the microscope. The part insoluble in alcohol is again submitted to the action of water, which takes up the aqueous extract, and leaves a little albumen and some earthy salts. These are recognised after incineration. The watery extract is recognised after the evaporation of the water in which it was dissolved.

3. *Parts soluble in boiling alcohol.*—The substances dissolved by boiling alcohol separate as it cools; one is precipitated in

* Vol. vii. p. 71.

the form of a flaky cloud, the other remains in solution; the first is separated by filtration, the second by the evaporation of the alcohol. I shall speak presently of the properties of these substances.

4. *Parts insoluble in cold water, boiling water, and alcohol.*—This portion, which may be composed of fibrin, coagulated albumen, or mucus, is the most difficult to analyse; indeed there is no chemical method of recognizing the substances of which it consists, when they have been once altered by the successive boilings in alcohol and in water.

The analytical method which I have just set forth is copied from the one adopted by Berzelius, in examining the blood; it allows us to ascertain the immediate principles which compose pus, and to obtain an approximative notion of their proportions; but, like the method of re-agents, it fails in characterizing putrefied pus, and in showing the differences of various, syphilitic, tuberculous pus, &c. Hence, after having long adopted it, I was obliged to have recourse to more delicate methods, to resolve the problems that I had proposed for myself.

(c.) *Pus examined by the microscope.*—In using the microscope, I did not examine pus in its natural state; the results obtained by observers who had preceded me were not encouraging, and I thought that this method of experimenting, like the one by re-agents, would neither teach me the composition of pus nor the reason of its varieties. I conducted my investigations as M. Raspail advises—that is to say, by crystallizing the watery and alcoholic decoctions of pus on slips of glass, then studying the forms of their crystals in the microscope, and learning their composition from their form. To judge of the nature of the salts, I followed the delineations given by M. Raspail; but I must say, that several times during the examination of pus, as well as of other morbid products, I have met with crystalline forms which I could not refer to any known delineation, and consequently could not interpret, for want of a standard of comparison. To remove this difficulty it would be necessary to crystallize all the salts which one might imagine could be found in animal substances, to draw them, and then publish the delineations. I began this work, but more urgent occupations prevented my completing it. Until this shall have been accomplished by some chemist, the study of salts by the microscope will often give results incapable of being interpreted, and pathologists who examine morbid products by means of their salts, will see crystalline forms (as I have often done) without being able to determine what these forms represent.

In the actual state of our knowledge, microscopic, like chemical analysis, and like re-agents, can give but an imperfect notion of the composition of pus.

(d.) *Examination of pus by exposing test-papers to its vapour.*—I was led to the employment of this method by finding that it was impossible to produce a black tint by mixing together a solution of lead and fetid pus, while the same pus gave a very decided black tint to compresses dipped in this solution and applied to the abscess. It struck me that the precipitation of the albumen by the salt of lead masked the sulphureous tint, or rather prevented its production; and that if this salt of lead was exposed to the vapour of the pus, the sulphuretted hydrogen, by its volatilization, would produce a very sensible reaction. My supposition was confirmed by experience. To examine this vapour, the simplest and surest method consists in putting the pus into a phial, and applying successively to its orifice papers dipped in a solution of the salts of lead, mercury, antimony, deutoxide of tin, arsenic, &c. In this way all the re-actions produced by sulphuretted hydrogen may be recognized, without heating the pus, if it is very fetid, or by heating it in a water-bath if it is less so.

The examination of the vapour of pus will also enable us to detect ammonia, when this alkali is formed by putrefaction; for this purpose, turmeric paper, or litmus paper, reddened by an acid, must be exposed to the vapour; they should then be kept, to see if the change of colour which they have undergone diminishes by exposure to the atmosphere. Lastly, a rod dipped in muriatic acid is to be brought near the pus, or the sore which secretes it. If ammonia is present, white vapours rise, or show themselves more thickly on the surface of the rod dipped in muriatic acid.

Such are the methods of investigation which I have employed, with the assistance of M. Roux and other house-pupils of the Hôtel-Dieu, at Lyons; and I have applied them, for the last three years, to the study of every variety of pus that I could find. I might have given every experiment, with all its details, had it not seemed to me that this would have added to the dryness of my essay, without giving additional clearness to the facts which I am about to state. My experiments can be easily repeated; I wish this to be done, for by this alone can all doubts be removed as to their correctness.

SECT. II.—On the immediate Principles always found in Pus.

I intend here to speak only of pus which has not been in contact with the atmosphere, before it issues from the abscess.

From the details which I gave when treating of the method to be followed in chemical analysis, it appears that pus contains water, soluble albumen, the aqueous and the alcoholic extracts of meat, earthy salts, soluble salts (such as the hydrochlorates of soda and of ammonia), fatty matter, and fibrin; in short, all the elements of the blood, except the colouring matter.

I tried, with the assistance of all the re-agents which act upon soluble albumen, if that which is contained in pus had any characters differing from those of the albumen of blood or of white of egg; but I could find none.

The alcoholic extract of meat (the *osmazome* of Thénard) also seemed to me to have the same characters in pus that it has in blood and in muscle: I recognized it by its reddish colour, its taste and smell of meat, and its solubility in cold water, hot water, and alcohol. The aqueous extract of meat, likewise, appeared not to vary, whether obtained from pus or blood. In both cases I remarked its solubility in cold and hot water, its insolubility in alcohol, its brittle and semi-transparent appearance, and its insipidity when it was obtained dry, by the evaporation of its aqueous solution. These two extracts have been pointed out by Berzelius, as existing in pus as well as in the majority of animal substances.

As to the animal substances which can be discovered by incineration, I have recognised, as Schwelge did, phosphate of lime and oxide of iron. I have even been able to separate them without incineration, by drying that part of the pus which is insoluble both in water and alcohol, reducing it to powder, and macerating it in dilute nitric acid. This acid dissolves a little oxide of iron and phosphate of lime, substances which also exist in the blood.

The soluble salts have occupied more of my attention. M. Raspail has justly insisted upon the importance of studying them; and it is easy to see how much their proportions and their nature must modify the properties of pus. They are obtained, as separately as possible, by dissolving in alcohol the extract of the aqueous decoction of pus; but as alcohol would precipitate the re-agents employed to test the salts, it must be evaporated, and distilled water used in its stead. The aqueous solution thus obtained, when tested with the nitrate of silver, affords a copious, white, clotty precipitate, insoluble in nitric acid, but soluble in ammonia; it also throws down a precipitate when tested with the nitrate of protoxide of mercury, and with sulphuric acid affords white and acid vapours, which are condensed by ammonia. These re-actions show the pre-

sence of hydrochloric acid; but as the solution is hardly acid, it is evident that this hydrochloric acid is combined with bases. What are they? Potash disengages alkaline vapours which are condensed by hydrochloric acid, and which are, therefore, ammoniacal; the hydrochlorate of platinum gives no clear result, on account of the reddish yellow tint which the extract of meat communicates to the solution of salts, from which it is inseparable. The other re-agents teach us nothing. We must, therefore, have recourse to other methods of investigation, and, placing a few drops on a slip of glass, wait till they crystallize, and then examine them with the microscope.

I must here warn the student that M. Raspail's microscope is insufficient to distinguish clearly the salts which are then formed. From confining myself to its use, I often obtained no precise notion as to the salts of pus, or of other animal fluids. A compound microscope is absolutely necessary. When we attentively examine the soluble salts of pus with this microscope, we find, in the first place, cubic crystals, in which two of the opposite sides are uneven, sinking by a kind of steps formed by the impression of a pyramid with a square base; secondly, squares and parallelograms; thirdly, fern-like arborescence. A very clear idea of all these crystals may be formed by consulting plate 6 of M. Raspail's Organic Chemistry, fig. 12, *a, b, d*; and the description given by the author, at p. 536. With the help of these data I recognised the hydrochlorates of soda, of potash, and of ammonia, in the crystals of the aqueous solution of pus. These salts are always present, which will not surprise the reader, when he recollects that in every analysis the hydrochlorates of soda and of potash have been found in the blood, and that M. Raspail has shown by experiments, of which I have several times verified the accuracy, that the blood contains the hydrochlorate of ammonia. As it is impossible to separate by solvents the hydrochlorates of soda, potash, and ammonia, and as the fear of altering the salts hardly allows us to employ incineration, which would volatilize the hydrochlorate of ammonia, it is obvious that the proportion of the different salts discovered by the microscope can be judged of only by an approximative estimate. The proportions estimated in this manner have seemed to me to differ in the several varieties of pus, as will be seen further on, when I shall treat of serous, mucous, and other kinds of pus. I ought to mention, that the salts of which I have pointed out the crystals, have already been recognised in pus; the hydrochlorate of soda, by Jordan, Pearson, and Gendrin; and the

hydrochlorate of ammonia by M. Raspail, who has pointed out its importance, and shown that it exists in a great number of animal fluids. The examination of the fatty matter of pus, which is soluble in alcohol alone, led me to some experiments showing the relation which exists between the composition of blood and of pus. It is well known that Vauquelin, in his analysis of the brain, and of marrow, discovered two kinds of fatty matter containing phosphorus, to which he gave the names of white cerebral matter, and red cerebral matter. M. Chevreul, when analyzing the blood, ascertained that the fatty matter which can be extracted from it by means of alcohol and ether is identical with the fatty matter of the brain, and offers the same two varieties which Vauquelin had observed in the cerebral pulp. Denys, in his experimental researches into the nature of human blood (p. 109) confirmed the discovery of M. Chevreul, and found these same two substances in the muscles; and as Vauquelin had observed them in the chyle, and Braconnot in the liver, and they contained phosphorus, he gave them the name of phosphorated fatty matter, instead of cerebral fatty matter, dividing them, after the example of Vauquelin, into red phosphorated fatty matter, and white phosphorated fatty matter.

The properties of these fatty matters are easily recognized; if we take one of the substances containing them, for example the fibrin of the brain, it is sufficient, after drying and powdering it, to boil it in alcohol. The liquor, when filtered, remains clear as long as it is hot; but, on cooling, it becomes turbid, and deposits a white substance, soft and greasy to the touch, soluble in ether, and not growing red by heat; this is white phosphorated fatty matter. The alcohol, which has deposited this matter, is now evaporated; and after its evaporation there remains a fatty matter which becomes of an orange-red by heat, softens without melting, and makes paper transparent as oil does: this is phosphorated fatty matter. (For more details, consult Denys' Experimental Researches upon the Blood, p. 105.) These two substances, when suspended in water, make it turbid and milky, and give it the appearance of an emulsion; this emulsion does not coagulate by heat, in which it resembles milk, but differs from it in not coagulating either by pressure or by acids. Now the fatty matter extracted from pus by means of alcohol, have exactly the same appearance, the same re-actions, and are dissolved and precipitated by the same substances, as the fatty substances of the blood, like them, too, they form white emulsions, and when they exist in pus in considerable

quantity, it coagulates but imperfectly by heat, and preserves its milky tint even after boiling. It is this, without doubt, that led M. Dumas to reckon among the constituents of pus*, a substance resembling casein, a fact which cannot be disputed, if the word casein merely means a substance forming a milky emulsion not coagulable by heat.

The property which these fatty matters found in pus possess of forming emulsions, seems to me their most remarkable characteristic, and I shall therefore call them emulsive fatty matters (*graisses émulsives*), not venturing to call them *phosphorated fatty matters*, as Denys did those found in the blood; for when, after incineration, I tried to find the phosphoric acid which would have been produced by the phosphorus had there been any previously, I did not succeed; whether because it was really absent, or from some fault in the experiment.

As I have stated above, the constituents of pus whose existence it is the most difficult to determine, are those which are insoluble in cold water, hot water, and alcohol. When they have been separated by these menstrua from the substances with which they are mixed, the only way to examine them is to dissolve them in acids, or in alkalies, at an elevated temperature. These re-agents, however, alter them, and produce solutions in which the properties of the acid or the alkali mask those of the substance which they dissolve. Thus, whether we examine albumen coagulated by heat, or organizable fibrin, such as is found upon an inflamed peritoneum, or fibrin spontaneously precipitated in blood drawn from a vein, the products obtained from them through the re-action of acids or alkalies are exactly the same. These re-agents, therefore, are unable to distinguish between very different substances, between false membranes capable of organization, and merely dead matter, like coagulated albumen. They are not able to throw any light upon the substances examined with their assistance. Hence we see that those constituents of pus which are insoluble in water, alcohol, and æther, which must be dissolved to be more accurately examined, and which can be dissolved only in acids or alkalies, must in some measure elude chemical examination. These unexamined parts are derived chiefly from the opaque and whitish masses that swim in creamy pus, and from the clots found in cold abscesses, and which are sometimes called coagulated albumen, and sometimes tuberculous matter. These whitish masses, and these clots, coagulate spontaneously during the formation of pus, and are insoluble in cold water, hot water, and al-

* Andral, Anatomie Pathologique.

cohol; and therefore they are formed by fibrin, as Jordan and Gendrin supposed. Nevertheless, they are incapable of organization, while the fibrin of false membranes, and even that of the blood, can be organized. Does this difference prove a difference in chemical composition also? I think not. The fibrin of pus floats in serum; it does not adhere to living tissues, and is therefore unable to receive blood, and become vascular; it is in the condition of a layer of plastic lymph detached from an inflamed serous membrane; like the false membrane detached in this manner, it has lost its capability of becoming organized, but it may have lost it from purely physical causes, and without changing its composition. Nothing proves, therefore, that it is altered, or that it differs chemically from the fibrin of the blood.

A similar conclusion occurred to me from comparing each of the immediate principles of pus with the immediate principles of the blood; and if the authors who have treated of this morbid product have not been able, like me, to point out each article that enters into its composition, and show that its composition is the same as that of the blood, minus the colouring matter, it is because no one of them had completely analyzed it, and more especially because the true nature of its fatty matters was not known; the settling this last question being the really new part of my researches. I was long surprised at the facility with which pus is secreted; for while I considered it as a peculiar substance, without anything resembling it in the animal economy, I could not understand how every tissue and every inflamed organ was capable of producing it, and why every solution of continuity not healed by the first intention necessarily secreted pus. But the moment that its relation to the blood was analytically demonstrated, this facility of production no longer seemed strange.

We learn from physiology that fluids containing immediate principles not found in the blood, such as urea, or the resin of the bile, can be secreted only by organs of a complex nature, such as the kidneys and liver; while the fluids merely formed from the immediate principles of the blood can be separated from it by the simplest tissues. The separation of the serum by the cellular tissue and serous membranes is an example of this. But if it is true that the secretion of every immediate principle which does not exist in the blood supposes a complicated apparatus, how can we imagine that pus can be secreted by cellular and fibrous tissues, or, to speak more correctly, by a false membrane in a vascular state, if it contained any principle peculiar to itself? But as

soon as we know that blood, to be turned into pus, requires merely to be deprived of its colouring matter, we are not surprised that a simple apparatus can produce so slight a change; and if the phenomena is not explained, at least it is shown to be analogous to other ones.

Let us remark in general, that if every tissue, and every inflamed organ, is capable of secreting serum, organizable matter, and pus, it is because every inflamed organ receives blood, and blood contains all the immediate principles which form serum, organizable matter, and pus. Chemical analysis is called upon to establish many relations between morbid products, as well as to specify more clearly the differences between them. But let us continue the examination of facts; the applications to pathological physiology will multiply at every step.

[To be continued.]

A POSTSCRIPT

TO THE

FIRST OF DR. PHILIP'S LATE COMMUNICATIONS.

To the Editor of the Medical Gazette.

SIR,

It is observed in the first of my letters, that the facts which had been ascertained reduce the general laws of our frame to that simplicity which we so constantly find to characterise the works of nature, when we have obtained a correct knowledge of them. It has since occurred to me, that it would have rendered clearer both some parts of that letter, and of those which follow it, had the foregoing observation been illustrated by the following short recapitulation, which I hope you will be so good as insert, as a postscript to my first letter, in the next number of the MEDICAL GAZETTE.—I am, sir,

Your obedient servant,

A. P. W. PHILIP.

Cavendish Square,
Dec. 4, 1837.

It appears from all the facts referred to in the preceding communication, that there are four distinct sources of power in the more perfect living animal, having no direct dependence on each other, namely, those of the sensorial, the nervous and muscular powers, and the powers of the living blood; while the due structure of the organs of each more or less directly depends on the co-

operation of the functions of all those powers; for it appears from what has been said in that communication, and the works referred to in it, that, through the function of respiration, the aid of the sensorial functions themselves is as essentially, though not so directly, necessary to the maintenance of the due structure of all our organs, as those of the muscular and nervous powers, and the functions of the living blood.

From a review of the various facts referred to in my first letter, it is easy to perceive the manner in which these different powers assist each other in the formation and maintenance of our organs.

The living blood supplies the materials from which they are formed, and from which they derive the supply which is rendered necessary in consequence of the materials of which they are composed undergoing a constant state of change, from their being, by the functions of the organs to which they belong, gradually rendered unfit for the purposes of life. This is evident with respect to the living blood, when we compare the arterial and venous portions of it, because there we can better trace the chemical processes on which the changes depend, than in other functions of the same class. In the functions of another class, we find the laws of mechanics in operation.

Observation, without the aid of experiment, at once points out that the mechanical phenomena of our bodies obey the same laws with those of inanimate nature, and that the muscular fibre affords the power on which, in the animal body, these phenomena depend*.

The chemical power, it appears from the experiments referred to in the paper to which the present communication is a postscript, is supplied by the nervous system properly so called; and, as we might from the simplicity of nature in all her works have expected, this power, as appears from the experiments of Dr. Faraday†, compared with those to which I have referred, is here the same which effects the chemical changes of inanimate nature.

The sensorial powers supply sensation and volition, the only sensorial functions employed in the maintenance of the due structure of our organs, and consequently of life‡; for the failure of

any vital function is necessarily followed by that of all the rest.

When we turn to the sensorial functions, we find ourselves in a new world. The striking analogy which necessarily exists between the mechanical and chemical phenomena of the living animal, (which are regulated by the same laws which operate in the external world, essentially modified, however, by the vital principle which pervades all living parts,) and the phenomena of inanimate nature, here wholly disappears; because whereas, while the phenomena of the other functions are the results of the co-operation of their living powers with the powers of the inanimate materials of which they are composed, in consequence of which they are capable of immediate intercourse with the materials, and consequently with the operations of the inanimate world; the functions of the sensorial organs being those of their living powers alone, they admit of no direct intercourse with the materials, and consequently with the operations of that world. And in the paper so often referred to in the Philosophical Transactions for 1836, I have considered at length the beautifully simple means by which they are enabled indirectly to act in concert with those operations, between which and their functions there is nothing in common.

Such are the whole of the functions on which the life of the more perfect animal depends. In the paper just mentioned, their *modus operandi* in their various, and particularly their more complicated results, is detailed, and the observations and experiments on which each position is founded referred to.

REMARKS

ON

THE NATURE AND TREATMENT

OF THE

DIFFERENT FORMS OF PORRIGO.

By WALTER DICK, M.D.

[Continued from p. 332.]

"Dan l'appréciation des phénomènes que présentent les maladies, il faut toujours faire entrer en ligne de compte la structure particulière de l'organe malade."—*Alard, Nat. et Siège des Mal'* tom. ii. p. 257.

THERE is nothing, as a writer justly observes, which affords so fair promise of improvement in the management of

* Philosophical Transactions for 1836.

† Ibid. for 1832, 1833, 1834, and 1835.

‡ Ibid. for 1829 and 1836.

cutaneous diseases, as a due regard to the anatomy and different functions of the skin. Before, therefore, proceeding to the consideration of the different forms of porrigo, we deem it right to premise a short account of the anatomy of the hair and sebaceous follicles, as these, in our opinion, are the parts primarily affected in the disease just alluded to.

Breschet and Vauzeme, who may be said to be the first to have successfully examined the intimate structure of the skin, have not yet bestowed particular attention upon the sebaceous follicles and hair, so that we can derive no assistance from these laborious and precise investigators. Much that is said of the organs in question in books, is neither very satisfactory nor correct we think. In place of making personal observations, the authors of anatomical systems, when treating of the skin, too often blindly borrow from their predecessors, and take for granted, and describe, what they have neither seen, nor taken the trouble to look for. The following short description of the hair and sebaceous follicles is drawn up from notes of some observations, which we have recently made on the human skin and skins of some of the lower animals, chiefly of the cow and sheep. Brief as it is, I trust it will be sufficient for my present purpose. The constituent parts of the skin, we may be allowed to remark, are so minute, so difficult of examination, and therefore so liable to be misrepresented, that much caution and candour are requisite in their examination. With this conviction we have pursued our investigations, and have not advanced any thing, of the accuracy of which we were not perfectly assured. Nevertheless some of our statements may prove to be inaccurate; if so, we shall feel obliged by being corrected, as we write not for novelty, but from a desire of adding our mite to the general stock of knowledge, and of advancing the interesting, but too much neglected, study of dermatology.

Anatomy of the Hair.

That part of the hair enclosed within the skin, is the part whose exact anatomical relations it is most important to know. This part, in the scalp at least, generally presents the shape of the letter J—the dermal extremity of the hair being very slightly bent upon itself. The origin of the hair is in the subcu-

taneous tissue, and generally presents the appearance of a small, blackish body, of a roundish form. This body lies at the bottom of a piliferous cyst, and minute colourless filaments, apparently vessels, may be seen entering it. The dermal extremity of the hair, which is hollow for a little way, and softish, almost pulpy, is implanted on the roundish body just described—the *monticule* of Duvernay, as it has been called—the hollow, corneous part of the hair forming a kind of sheath round the monticule. The connexion between these two parts is not very strong, as the hair may, almost invariably with a little dexterity, be plucked out, without bringing along with it the monticule.

Each hair is enveloped in two sacs. The inner one is very delicate, and closely applied to the hair, especially a little below what is called its neck. The outer sac is thicker and stronger than the former. The two are but slightly connected, and are easily separated from one another. Morbid action in either of them, especially when producing effusion of fluid, would very likely intercept the nutriment of the hair, and cause it to fall out, or separate from its attachments.

In what way hair is produced has not yet been determined. It is not yet ascertained, I believe, whether the inner piliferous cyst is immediately concerned in its production, or whether the monticule secretes both the corneous substance of the hair and its colouring matter. That the monticule is principally concerned in the production of hair, is evident from the fact, that no hair is ever generated after its destruction. But it seems probable to us that two different structures are concerned in the production of an entire hair, as we sometimes see the hairs become blanched, while they remain otherwise natural and continue to grow. This, we think, could scarcely happen if the same organ produced both the corneous part of the hair and its colouring matter.

Some writers have asserted that the hair receives a covering from the cuticle. They suppose that that membrane passes down the piliferous cyst to its bottom, and is there reflected along the hair. Others have fancied that the hair, after rising to the level of the cuticle, pushes it before it, and thus, as it were, mechanically takes a covering from it. The fallacy of these views has been success-

fully exposed by Bichat*. The cuticle does not seem to be reflected at any part along the hair, but is more or less firmly attached to it at its exit from the skin, and passes only a little way down the inner piliferous sac. It is a curious fact that the cuticle, though permeated by myriads of hairs, sebaceous follicles, and sudoriferous canals, does not, when separated from the chorion, present a sieve-like appearance, as might have been expected. Various explanations have been given of this phenomenon: the most satisfactory seems to be Mr. Cruickshank's, who ascribed the disappearance of the pores in the detached cuticle to the elasticity of the membrane†.

Hair, when seen through a powerful microscope, presents the same appearance as the cuticle; and analysis has proved that the chemical components of these two structures are nearly the same. It is highly probable, we think, that hair is formed, like the cuticle, by two different sets of organs; one set secreting the corneous substance; the other, the colouring matter. Some authors, and amongst these Bichat, have supposed that hair possesses a certain degree of vitality; and as confirmatory of this opinion, they adduce the phenomena of *Plica Polonica*. This view, however, seems to be erroneous; and the phenomena of *Plica* can be satisfactorily accounted for, by referring the seat of the disease to the piliferous bulbs and cysts.

Anatomy of the Sebaceous Follicles.

The sebaceous follicles are organs familiarly talked of, but their true structure, I suspect, is but imperfectly known. They are easily seen in the cow's skin; and we may be allowed to state a few particulars respecting their appearance in that animal, before describing those of the human skin. In the cow they bear a striking resemblance to the Meibomian glands, with this difference that they are much smaller, and their central canal or duct is not a shut sac, but is continuous with the piliferous cyst. Each piliferous cyst may be said to be surrounded at its summit by one of these follicles, the follicle being on

the outside of the double pilous sac. Such is the usual appearance of the sebaceous glands in the cow's skin. But there is a peculiarity at the roots of some of the hairs worthy of notice. Interspersed amongst the shorter hairs, there are many longer and stronger ones. The roots of these latter hairs are enveloped by two cysts—an outer one, very thick, and of a fibrous texture; and an inner one, of a delicate diaphanous structure. Between these two cysts an erectile or vascular tissue is situated, which throws out a drop or two of blood when cut into. The sebaceous follicles belonging to these coarser hairs are considerably smaller than those round the finer hairs; and in place of lying outside of the pilous cysts, are situated between the fibrous and inner cysts, being attached principally to the former.

The sebaceous follicles of the human skin are smaller, less complex apparently in their structure, and consequently more difficult of examination than those of the cow; but their relative situation is the same. They are best seen at the roots of the cilia or eyelashes, elsewhere they are smaller, but essentially the same in structure. On the nose, where their orifices are usually pretty perceptible, especially in males, we see delicate or rudimentary hairs passing out from many of the orifices, and frequently by pressure we may force a little sebaceous matter along the hairs, or out by their sides; satisfactorily enough, establishing that the hairs pass through the centres of the follicles, and that the pilous cysts and sebaceous follicles have a common outlet*.

Mr. Chevalier states, in his lectures, delivered some years ago before the College of Surgeons, London, that there are two sets of sebaceous glands in the human skin:—1st, a superficial set, “between the second epidermis and the cuticle, to which they appear very firmly attached;”—2d, “A deeper set embedded in the chorion, and which are commonly known as the sebaceous glands.” This discovery of Mr. Chevalier has not, we believe, been confirmed by any subsequent anatomist.

* Anat. Générale, tom. iv. Système Pileux.

† According to Breschet, the sudoriferous canals, which are of a spiral form, pass through the cuticle obliquely; they are torn, and their fragments attached to the cuticle shrivel up, when that membrane is detached from the corion. In this way, M. B. satisfactorily accounts for the disappearance of the sudoriferous pores.

* It is the sebaceous follicles, we believe, which produce that peculiar, transitory appearance of the skin, denominated *cutis asserina*. Some have thought that it resulted from the bulbs of the hair, but we do not see how these, seated as they are beneath the cutis, could give rise to the appearance in question.

We learn from Alibert*, that Eichhorn, from having observed that "*tannes*," or grubs, escape from the apertures which give exit to the hairs, denies the existence of sebaceous glands, and supposes that the function commonly ascribed to these organs is performed by the piliferous cysts. After what has been said above, we need say nothing in refutation of this opinion.

The sebaceous glands lubricate the hairs, and soften the skin, by their secretion; and they may, perhaps, be subservient to more important purposes in the animal economy than physiologists are at present aware of.

Porrigo Lupinosus†.

This variety of porrigo is well named, from the peculiar form which its characteristic scabs present. Indeed, in the whole catalogue of skin diseases, there is not, perhaps, one more happily named, as its scabs bear a striking resemblance to lupine seeds:—hence the epithet, *lupinosa*. M. Baudeoque believes that these cup-shaped scabs are not the products of pustules, but of a morbid secretion from the piliferous cysts. M. Mahon, whose opportunities of observing the disease have been very numerous, also denies their pustular origin.

* Monographie des Dermatoses, tom. ii. p. 68.

† Achores and Favi are two varieties of pustules, frequently mentioned by writers when describing the eruptions of the scalp. The latter (Favi), as described by Willan, differ in no respect from the psudria: but the achores appear to be a distinct species, and are therefore entitled to special notice.

An English student, who is familiar only with Willan's nomenclature, is apt to be perplexed by finding the terms favi and achores used in a different sense by French writers. The pustules characteristic of *P. lupinosa*, are called by Willan and Bateman, achores; while by the French dermatologists they are styled favi; and hence *P. lupinosa* is called, by the French, *P. favosa*, or *teigne favieuse*—a disease very different from the *P. favosa* of Willan. The French, however, are entitled to the credit of having described the pustules in question more minutely and accurately than either Willan or Bateman, and had they retained Willan's term, they would have prevented the confusion to which they have given rise, by using a different appellation.

The achores of Alibert, Bielt, and others, are nearly synonymous with the favi of Willan.

It is well known that Dr. Willan borrowed the above terms from the ancients, and if ancient usage can go for any thing in such matters, he certainly used them in their proper sense, the achores being anciently reckoned the smaller, the favi the larger, species of pustules.

In the article "Achor," in the Cyclop. of Pract. Med. no mention is made of the discrepancy exhibited in French works in the use of the above terms; and as we ourselves were, for a time, somewhat puzzled by this discrepancy, the above remarks may perhaps prove serviceable to others under similar circumstances.

"Des observations attentives et mille fois répétées ne me permettent pas de regarder la teigne favieuse (*Porrigo lupinosa*) comme une eruption pustuleuse*."

M. Mahon has been led to believe that the disease originates in the sebaceous glands, and that the cup-shaped scabs which it presents result from the indurated secretion thrown out from these organs. We are inclined to take the same view of the disease; and we have a preparation in our possession which we think establishes it. The phenomena of the disease, we will venture to affirm, are more satisfactorily accounted for by this view of its pathology than by any other.

Porrigo lupinosa, when seen at its very commencement, presents small yellowish points, depressed in their centres. These achores, or, as the French call them, *favi*, are almost invariably traversed by hairs. Their contents, moreover, almost from their very commencement, are concrete. They enlarge slowly, seldom exceeding three or four lines in diameter, although they are sometimes seen as large as a sixpence. During their development the cuticle covering them cracks, and partially falls off. They are firmly imbedded in the skin, and when fully formed still retain the circular form, raised at the edges, and cupped. These peculiar scabs are usually of a light yellow colour, and when of old standing a powdery substance is seen lying in their central depressions. They arise usually distinct from one another, but during the progress of the disease they sometimes run together, forming one or more large, elevated, indented scabs. The skin between the scabs seldom appears reddened, but very frequently presents a furfuraceous appearance. The hair very generally becomes lighter coloured, and brittle on the affected parts, and either falls off spontaneously, or may be removed with facility, and without causing pain.

When the scabs are removed by means of poultices, the parts upon which they lay appear raw and excoriated, and depressed; a viscid fluid is speedily thrown out, which concretes into scabs, irregular in their form, and altogether different from the primary ones.

Sometimes, in severe and neglected cases, the scalp becomes deeply ulcerated,

* Recherches sur les Teignes, p. 6.

even so as to expose the cranial bones; and a most abominable smell is exhaled from the scabs in those cases where cleanliness is not observed. Pediculi are likewise generated in great abundance. The cervical glands not unfrequently become enlarged and painful; and in neglected cases the system occasionally suffers so much, that the body is stunted in its growth, the development of the intellectual faculties is retarded, and a state of cachexia induced which sometimes terminates in death.

Porrigo lupinosa is not confined to the scalp, but may appear on any part of the body. Alibert mentions a case where the eruption was diffused over the whole body, the scabs on the trunk and extremities presenting the same cupped appearance as those on the head.

From each of the scabs in *P. lupinosa* being permeated by a hair, Mr. Plumbe and others have been led to believe that the hairs play an important part in the production of the scabs. Duncan, Underwood, and Luxmore, have even asserted that the disease originates in the bulbs of the hairs. This opinion, we think, has been successfully combated by Murray, who found these organs at the commencement, as also sometimes during the progress of the disease, in a healthy state. Murray remarks, "*potiorem sedem mali in folliculis dictis pinguetudinis, vel ipso textu celluloso, quaerendam arbitror.*"

M. Baudelocque, who denies the existence of sebaceous follicles in the scalp, places the origin of the disease in the pilous cysts. "This opinion," says he, "I have deduced from the disease most frequently attacking those parts which are most plentifully supplied with hair; from the non-existence of sebaceous follicles in the scalp, as Bichat, Meckel, and others, affirm; and from one or more hairs almost constantly traversing the *faveous* scabs*."

The opinion respecting the seat of *P. lupinosa* which we have already stated as the one we are inclined to adopt, could not be entertained, were it true that the scalp contains no sebaceous glands. But if we are not much mistaken, we ourselves have seen these organs in the scalp, and are therefore convinced of their existence. They are placed, as we observed above, at the exit

of the hairs from the skin, and surmount as it were the summits of the pilous cysts. Their ducts give exit to the hairs, and communicate inferiorly with the pilous cysts.

The preparation to which we above alluded as confirmatory of the opinion of the disease being seated primarily in the sebaceous follicles, consists of a small portion of the scalp, inclosing an incipient lupine-like scab, taken from a subject who died of fever, and who had, for a considerable period before death, been affected with *P. lupinosa*. The scab is seen to be still covered by the cuticle: inferiorly, it appears to be inclosed in a membrane, and a hair enveloped in its double cyst, apparently in a healthy state, is seen passing through its centre. In short, the scab occupies exactly the situation of a sebaceous gland, and appears to be neither more nor less than a sebaceous gland distended by a concrete secretion. This view of the pathology of the disease seems to be confirmed by the fact that when a lupine-like scab is removed it is not succeeded by a similar one, but by one of an irregular form, without the peculiar cupped appearance. This arises, as we conceive, from the sebaceous follicle having been destroyed during the development of the primary scab.

From the intimate connexion of the pilous cysts with the sebaceous glands, the former very generally become diseased when the latter organs are in a morbid state; and it is from this cause, we think, that the hairs become altered in appearance in *P. lupinosa*. Permanent baldness is not unfrequently occasioned by this disease, and it results, as we remarked before, from the total destruction of sebaceous glands, pilous cysts, and *bulbs*.

There is a variety of *P. lupinosa*, where the *achores* (*favi* of the French) arise closely set together in patches of a circular shape, and ultimately become transformed into large, elevated scabs, irregular on their surface, but without the indentations exhibited by the scabs of the former variety of the disease. It is the pressure which the *achores* mutually exert upon one another, when thus crowded together in clusters, that prevents them from individually presenting the cupped appearance which they present when arising distinct and separate from one another, as in the common *P. lupinosa*. Alibert describes this form

* Recherches sur la Teigne faveuse; Revue Medicale, t. iv. 1831.

of porrigo under the name of *Favus scutiforme*; and correctly observes that it is essentially the same as *P. lupinosa*. It has also been described by some under the term *P. scutulata*, but in my opinion it is quite a distinct disease from the *P. scutulata*, or ringworm of this country. For the sake of distinction, it might be called *P. lupinosa conferta*.

The two forms of *P. lupinosa* above described are those, in our opinion, which are seated primarily in the sebaceous glands. We have next to describe those which primarily affect the pilous cysts, and parts which secrete the hair *

[To be continued.]

SOME ACCOUNT OF MESMERISM.

BY BARON DU POTET DE SENNEVOY.

[Continued from page 379.]

Report of the French Academy, in 1831.

FIVE years had elapsed, and the committee had not yet accomplished its task. Some anxiety was already felt as to the motives of so long a delay, and fears were conceived lest there should be a denial of justice on the part of the commissioners. Several magnetisers had presented facts to their notice, and accounts had been drawn up; and I also had placed myself at the disposal of the members of the commission. They had met at my residence several times to witness experiments, and I had received their promise that the effects produced before them should be acknowledged.

Magnetism continued to spread among those who are usually strangers to scientific researches. Astonishing phenomena were produced, before persons incapable of appreciating the importance of their own works. Somnambulism, a phenomenon of which we shall presently have to speak, was prostituted. The wife of a shoe-maker (*La Fanchouquet*) was spoken of, as having been thrown into somnambulism by her husband, and relating, while in that state, the scenes of a new kind of existence (*les scènes d'une vie nouvelle*.)

Another patient, a blind man (*Lemaire*), having become a somnambulist in consequence of magnetisation, attracted round him all the inhabitants of

his district to witness his ecstasies, and, indeed, this singular phenomenon was being produced in all quarters. Meanwhile, what were scientific men about? They were occupied in disputing the possibility of a phenomenon which was matter of common notoriety; they denied the existence of a force which was essential to life. It was in the very sanctuary of science, and in the deepest meditation, that they ought to have examined into it; but they only laughed at the credulity of those who invited them to do so.

But very soon magnetism emerged from its obscure retreats: for gilded equipages went to seek it there. The princess N—— was seen to reward liberally the services which she believed herself to have received from a somnambulist. The Comte de —— caused the wonders of which he had been witness to be inserted in a journal. No doubt their sole object was to make known these facts, and to recompense some real service. Charlatanism however sprang up. Avarice took possession of somnambulists, and they had recourse to deception. Very soon, serious causes were brought before the tribunals, in which magnetism had been employed as a means of abusing the confidence of respectable persons. Several celebrated magnetisers of that period were called upon by the judges to enlighten them on the subject of their art.

The theatre availed itself of somnambulism; a drama was represented, in which the principal character being magnetised on the stage, sleep and reveals a crime which he had committed, during a species of natural somnambulism. This bold attempt of the author was favourably received by an audience already familiarised with this new art.

The novelists were not behind-hand. Frederick S—— introduced magnetism into his romances; and our celebrated Pigault le Brun warmly undertook the defence of a truth which, on its first appearance, he had attacked; a remarkable circumstance, proving the progress that magnetism had made, French literature, in reality, took a hue of magnetism.

The avowals about to be made by the committee had thus become more easy and less dangerous. The commissioners, therefore, announced to the Academy that they would read their report on the 21st of June, 1831.

* Errata.—In p. 331, col. 2, l. 1, omit "P. scutulata;" and in p. 332, l. 6, omit "profession."

The hall in which the Academy assembled (so empty on ordinary occasions,) was crowded that day. Even the passages were obstructed by the curious. One would have said, that one of those decrees on which the weal or woe of a nation depends, was in agitation. All the members of the Academy, even those enfeebled by age, were at their posts.

At length the meeting was opened, and M. Husson, the reporter of the committee, appeared at the bar with a voluminous roll of paper. This was a good sign. It implied that they had investigated the subject.

He spoke in a grave and measured tone, and began by reviewing the events which had preceded the nomination of the committee; then he invoked the memory of the ancient friendship borne by the elder practitioners present, to the members of the committee. At length he came to the point: he related first all that had appeared doubtful to the commissioners; he then cited the facts which could be explained by causes foreign to magnetism. At length came the turn of the more positive facts. But as the forms of oratory, and the cases already cited, had absorbed much time, the conclusion of the report was deferred till the next meeting.

That was the day of the grand battle;—I say battle, for on that occasion there was a general affray amongst the members of the Academy.

I am now, Mr. Editor, going to quote some facts mentioned in the report. Those who attested them are yet living; they still sit in the Academy. If these were false, the physicians who gave them as being true are unworthy of their seats in that scientific body: if they suffered themselves to be deceived, if they were the dupes of a piece of jugglery, what value is to be set on human penetration?

On the 27th of October, 1827, I was called by the committee to make experiments upon some patients at the academy itself. No patients were there. It was an ingenious mode of inviting me to practise on the commissioners. I complied with pleasure. M. Itard, physician to the deaf and dumb, and a member of the Academy, was the first who submitted himself to magnetisation. The following are the words of the report:—

“A more decided magnetic action

was observed on a member of the committee, M. Itard, magnetised by M. Du Potet; he felt a heaviness without sleeping, a decided *agacement* of the nerves of the face, convulsive motions in the ale of the nose, in the muscles of the face, and of the jaws. A flow of saliva in the mouth, which had a metallic taste, a sensation similar to that which he had experienced from galvanism. The following experiments excited cephalalgia, which lasted several hours, and at the same time the habitual pains greatly diminished.”

The reporter adds,

“It is not upon men of our age, and, like us, always on their guard against the errors of our *esprit* and of our senses, that imagination can have much influence. At our period of life it is enlightened by reason, and freed from those illusions by which youth is so easily seduced: at our age it is ever on the watch, and distrust, rather than confidence, presides over the various operations of our minds. These circumstances are happily united in our colleague, and the Academy knows him too well not to admit that what he professes to have felt he really did experience,” &c.

The committee met on the 10th September, 1827, at seven o'clock in the evening, at the house of M. Itard, to continue the experiments on Cazot. “The latter was in the apartment of this physician, where he was engaged in conversation till half-past seven; at which moment M. Foissac, who had arrived subsequently to him, and had remained in the antechamber separated from him by two closed doors, and at a distance of about twelve feet, commenced magnetising him. Three minutes after, Cazot said, ‘I think that M. Foissac is there, for I feel stupified.’ At the end of eight minutes he was fast asleep.”

This experiment was made to ascertain whether magnetism acted at a distance, which all magnetisers affirm to be the case. The following are the trials made to convince themselves that Cazot was not practising deception. Page 54 of the Report:—“Cazot being asleep, a phial full of ammonia was applied three times to his nose, but he did not awake.”

“M. Fouquier thrust a pin, an inch deep, into the forearm; another was introduced obliquely under the sternum, to the depth

of two lines; a third also obliquely into the epigastrium; a fourth perpendicularly into the sole of his foot. M. Guersent pinched his forearm so as to leave an ecchymosis. M. Itard leant upon his thigh with the whole weight of his body. They endeavoured to excite a tickling sensation by passing a small piece of paper under his nose, on the lips, the eyebrows, the eyelids, the neck, and the sole of the foot; nothing could awake him."

The following operation, inserted in the Report, and which I shall quote at full length, strongly corroborates the real existence of this state of magnetic sleep:—

"You have all heard a fact spoken of, which fixed the attention of the section of surgery, and which was communicated to it at the meeting of the 16th of April, 1829, by M. Jules Cloquet. The committee has thought it necessary to record it here, as one of the least equivocal proofs of the force of the magnetic sleep. The patient was a lady, Mad. P—, 64 years of age, residing at No. 151, Rue St. Denis, who consulted M. Cloquet, on the 8th of April, 1829, for an ulcerated cancer in the right breast, which she had had for several years, and which was complicated with a considerable enlargement of the corresponding axillary glands. M. Chapelain, her ordinary physician, who had been in the practice of magnetising her for some months, with the view, as he said, of dispersing the swelling of the breast, had not been able to obtain any other result than that of producing a very profound sleep; during which sensibility appeared to be annihilated, while her ideas retained all their lucidity. He proposed to M. Cloquet to operate upon her during the state of magnetic sleep, and as the latter considered the operation to be indispensable, he consented, and it was fixed for the following Sunday, the 12th of April. During the two days preceding that of the operation, the lady was magnetised several times by M. Chapelain, who, whilst she was in the state of somnambulism, prepared her to submit without fear to the operation, and had even brought her to converse upon it with confidence, although, in her waking hours, she rejected the idea with horror.

"On the day appointed for the operation, M. Cloquet, on his arrival at half-

past ten in the morning, found the patient dressed and seated in an arm-chair, in the attitude of a person in a tranquil natural sleep. She had returned, nearly an hour previously, from mass, which she was accustomed to attend at that time. M. Chapelain had thrown her into the magnetic sleep after her return, and she spoke with much composure of the operation she was about to undergo. All the arrangements being made, she undressed herself and seated herself in a chair. M. Chapelain supported the right arm: the left was allowed to hang down.

"M. Pailloux, *élève interne* of the Hôpital St. Louis, was employed to present the instruments, and to tie the vessels. The first incision, commencing at the axilla, was carried round the upper part of the tumor as far as the inner border of the breast; the second, beginning at the same point, was carried round the lower part of the tumor, till it met the first. The enlarged glands were dissected with precaution, on account of their vicinity to the axillary artery, and the tumor was extirpated. The operation lasted from ten to twelve minutes.

"During all this time the patient continued conversing tranquilly with the operator, and did not give the slightest indication of sensibility; no motion of the limbs, or of the features—no change in the respiration, or of the voice—no emotion even in the pulse, could be perceived: the patient never ceased to be in that state of automatic *abandon* and impassibility in which she had been for some minutes before the operation. It had not been requisite to hold her; they only supported her. A ligature was applied to the lateral thoracic artery, which was opened during the extraction of the glands, and the wound being closed by adhesive plasters and dressed, the patient was put to bed, still in a state of somnambulism, in which she was allowed to remain forty-eight hours. An hour after the operation a slight hæmorrhage appeared, which, however, proved of no consequence. The first dressings were removed on the following Tuesday (the 14th); the wound was cleansed and again dressed, the patient not testifying any sensibility or pain; the pulse preserved its ordinary character. After this dressing, M. Chapelain awakened the patient, whose somnambulant sleep had lasted

from an hour before the commencement of the operation—that is to say, during two days.

“This lady did not appear to have any idea, any *sentiment*, of what had passed; but on learning that she had been operated upon, and seeing her children around her, she was greatly agitated; which the magnetiser put a stop to by immediately sending her to sleep.”

The assertions of the reporter continued:—He cited the history of a somnambulist who had been observed by the committee. This man was sensible at a distance to the action of his magnetiser, who by the sole power of his will was able, when a written order for the purpose was given him, to produce in a part, also designated, very decided convulsive motions. He was awakened, and again cast into sleep, without being touched. The precautions taken to prevent all trickery were given in full detail to the Academy, by the commissioners, who were anxious to show that they had been good observers. But when they stated that this man, during his sleep, had played at cards with several of the members of the Academy, and that he had won of them all, although several endeavours had been made to cheat him, and when they related many other proofs of great lucidity, a general murmur was excited not very flattering to the commissioners. They were first taxed with exaggeration; then the penetration of men whom the Academy had till then held in distinction was called in question. It was yet much worse when the reporter recounted facts still more strange than those already quoted. Several academicians started from their seats, and apostrophised in coarse terms the men who had come conscientiously to relate to the Academy that which they had seen and attested.

An outcry was raised on all sides against the committee; but without being disconcerted, those members of the Academy who believed in magnetism, because they had themselves examined into it, supported the members of the committee. They replied to their antagonists—You do not believe in magnetism; be it so; but in this very place the circulation of the blood was denied; yet the blood does circulate. In this place the physicians who first employed tartar emetic were put on their trial; they were expelled from the Academy; and now we have for colleagues men

who employ it in enormous doses*. Another exclaimed, with a stentorian voice—the institution ridiculed during a considerable time the men who affirmed that they had seen stones fall from the sky; and yet stones do fall. They recalled also the history of inoculation. A deliberation was cited, held by the Academy of that period, in which inoculators were declared cheats and charlatans, and the inoculated, dupes and fools.

At that moment the sanctuary of science had become an arena in which the passions were let loose. Reason had lost her empire. They ought to have judged coolly, and listened to men who were known to be honourable persons; but they suspected the rectitude of their intentions. The meeting continued in the midst of extreme noise and agitation. It was necessary, however, to terminate the discussion. The first question agitated was, whether the report should be printed. It was decided in the negative; but as each member of the Academy wished to have a copy of so extraordinary a report, they were unanimous in deciding that only a very small number of copies, besides those required by the members, should be lithographed.

For a considerable period this report was the universal theme; but, strange to say, the press this time remained a stranger to the discussions which took place; or rather, it declined interfering with them. It feared, no doubt, that it was not sufficiently enlightened on the subject.

I ought here to speak of the facts which met with so much incredulity, and which the Academy would neither adopt nor reject, for it separated without coming to any conclusion, and no one had the boldness again to bring forward the question. These facts will find a place at the conclusion of the history of magnetic somnambulism, of which I shall give an abridgment. But before this narration, allow me to make some reflections. I am so fearful that the truth will be doubted, that I would anticipate in the minds of your readers the objections that may be excited in them by the new phenomena I am about to present to them.

What would they have replied, before

* At that period Becamier administered tartar emetic in doses of 20, 40, 80, and up to 160 grains.

the discovery of the laws of electric and galvanic action, to any one who had assured them that the friction of resinous substances and glass could, by the contact of two metals suitably disposed, produce the astonishing phenomena now universally known? They certainly would not have failed to treat such a man as a visionary—an enthusiast—and to have considered the result of positive experiments as errors unworthy of refutation. Let them take care not to commit a similar error with respect to magnetic somnambulism. If the contact of two pieces of metal, the friction of glass or resinous substances, bodies of which the properties are at an incommensurable distance from those of a nervous system and of the human brain, are capable of bringing forth such extraordinary phenomena, why should it be inconceivable that two nervous systems—two brains placed in certain relations with each other—should be able to produce a change in the ordinary state of these organs, from which the phenomenon of somnambulism results?

That which I present here as an hypothesis is about to become as positive a truth as that which is now so fully established in the belief of all. As difficult as it would be to demonstrate that electrical phenomena do not exist, so difficult would it be to prove to us that we are in error, for our judgment rests on facts as firmly established.

Magnetic somnambulism, the most curious phenomenon recorded in the history of science, will soon open a vast field to observers. We are hitherto scarcely acquainted with it; yet we are already beginning to rectify errors which have long been adopted as truths; and we already inquire, what will become of the knowledge we have amassed with so much labour and care, if it be true that individuals plunged into somnambulism have a particular mode of existence, senses peculiar to that condition, a distinct memory, and an intelligence more active than in the waking state!

Until Mesmer, the human intellect had not yet thought of carrying further the external operation (*l'extérieur*) of our senses, except by augmenting the condition of the sensations; that is to say, by augmenting the internal effect (*l'intérieur*) of the action which objects exercise upon us. It is this which took place by the invention

of optical instruments (microscopes and telescopes.) By this means the darkness has been penetrated which concealed from us an entire universe of infinitely small and infinitely great objects.

To what an extent has not philosophy been benefited by this ingenious discovery! What absurdities has it not demonstrated in the ancient systems of the nature of bodies, and what new truths has it not rendered perceptible to the attentive eye of the observer!

What would the genius of Descartes, of Galileo, of Newton, of Kepler, of Buffon, have produced, without the extension of the organ of sight? Great things, perhaps; but astronomy would have remained almost stationary, and even natural history would have made but little progress. If the extension of one of the senses has been able to produce a considerable revolution in our knowledge, how much vaster a field is about to open to our observation, if, as it is affirmed, the extension of the intellectual faculties can be carried farther than optical instruments have carried the extension of sight.

[To be concluded in another article.]

NOTE FROM MR. SOLLY.

To the Editor of the Medical Gazette.

SIR,

You have done me justice in assuming that the evidence attributed to me by the *Times* newspaper, in the case of Charles Morris, was an error on the part of the reporter. This I supposed must have been too evident, even to the unprofessional reader, to require correction. I have nothing to do with the merits of the case, in either a legal or political point of view. I was called upon by the clerk of the Board of Guardians to make a post-mortem inspection of the body, and to give evidence before the coroner as to the cause of death. I received no information as to his previous history, so that my mind was left wholly unprejudiced, and my evidence was founded solely on the postmortem appearances, the statements relating to his condition, which were given on oath before the coroner.

The following is a copy of my notes, taken by my pupil, Mr. Alfred Taylor, while I conducted the dissection of the body:—

Nov. 24, 1837, half-past 7, P.M.
Clapham Workhouse.

*Postmortem Appearances found in the
Examination of the Body of Charles
Morris.*

External appearances.—Body plump and healthy; under surface dark-red, from gravitation of blood; an open boil on the inner side of the left thigh, just above the condyle.

Head.—Dura-mater perfectly healthy; vessels of the pia-mater rather fuller than usual, but the arachnoid natural; septum lucidum, and anterior part of the fornix, a little softer than usual.

Chest.—No adhesion of the pleura, or unnatural appearance on the right side; very slight and old-standing adhesions on the left. Congestion of the vessels of the mucous membrane of the trachea and bronchial tubes; fluid in all the smaller tubes; lungs crepitate throughout, but contain a large quantity of watery fluid. Pericardium healthy; both ventricles of the heart full of blood; the wall of the left ventricle thick, but not much more so than is usually found in a strong muscular man. A small firmish deposit, about the size of a split pea, on the posterior flap of the mitral valve.

Abdomen.—Peritoneal surface healthy. Bladder full of urine, but not unnaturally distended. Mucous membrane healthy throughout. Liver full of blood; kidneys the same; spleen soft.

I remain, sir,

Your obedient servant,

SAMUEL SOLLY.

1, St. Helen's Place, Bishopsgate-street,
Dec. 5, 1837.

MEDICAL GAZETTE.

Saturday, December 9, 1837.

“*Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso.*”

CICERO.

THE BRIDGWATER UNION.

THE satellites of the Poor-law Commissioners, by the barbarous zeal with which they obey the edicts of their stern

taskmasters, are most assuredly preparing the way for a mitigation, if not a repeal, of the Malthusian Act. Their conduct is every way revolting to the sense of justice as well as of humanity for which this nation has ever been celebrated, and reminds us of the trite but deep adage which asserts, that Providence deprives of their senses those whom it intends to destroy. We doubt, therefore, whether the triumvirate are always gratified with the reckless ardour of their subalterns; for this constant and open defiance of all the decencies and charities of life has a strong tendency to shorten the existence of some of the snuggest salaries going. Hence, as we stated in our number of October 14, when three little children had been put in the stocks, whipped, and starved, in order to cure them of diarrhœa proceeding from weakness, the potent three actually went so far as to disapprove of it: hence, too, although as Malthusians they are bound to believe that pauperism is the great canker eating into the vitals of the nation, we doubt if they will have the courage to bestow a civic wreath (*ob civem trucidatum*) on the men of Clapham, who milled a sick pauper, as we detailed in our last number, and thus cut out a bit of the national gangrene. Lastly, we more than doubt whether our dictators will venture to bestow any applause on the guardians of the Bridgwater Union, who, though they saved at least fifteen shillings at the expense of not more than two or three lives, yet fell into a money-trap which they had baited for their surgeons; and being indebted to them some two hundred and odd pounds, seem likely to appear in no very enviable position in the Court of Queen's Bench.

The conduct of the Bridgwater people, indeed, has been so curious throughout, that we feel inclined to make our readers acquainted with it, as we find it

detailed in a pamphlet now before us*. When the Bridgwater Union was first formed under the new Act, in 1836, the forty parishes of which it consisted were divided into seven districts; and these were placed under the care of seven surgeons (all legally qualified to practise), at salaries varying from 100*l.* to 25*l.* A fee of ten shillings was allowed for every case of midwifery attended by an order from a competent authority.

At the end of the year the Board of Guardians determined to increase the number of districts from seven to nine, and published a notice giving the divisions of the new districts, and the salaries offered for each, varying from 70*l.* to 30*l.* per annum. One of the 30*l.* districts was that of Polden, containing a population of 2240; another that of Cannington, containing 2394; and a third, the Union Workhouse itself. On this last the authors of the pamphlet observe, that—

“The Union house is calculated to contain 300 persons. The salary offered to the medical officer was 30*l.* a year, or one shilling and sevenpence-halfpenny a day. In the miscellaneous estimates presented to the House of Commons, May 30, 1836, are the following items:—Twenty-one Assistant Commissioners, 700*l.* a year each, 14,700*l.*; their travelling and incidental expenses, including clerks, 800*l.* a year each: 16,800*l.* Each Assistant Commissioner, therefore, is charged to the country 1500*l.* a year, or 4*l.* 2*s.* 2*d.* a day; whilst nineteenpence-halfpenny a day is considered a proper remuneration for an expensively educated medical man, intrusted with the lives of hundreds of his suffering fellow-creatures*.”

This is well put, for it is scarcely possible to conceive a stronger contrast than exists between the reward of the Assistant Commissioner, who can live with great comfort, and yet lay by at

least two-thirds of his salary, and that of the district surgeon, who, if he did his duty efficiently, would find the whole of his time occupied, while his salary would not pay for his medicines. The truth is, that whatever political economists may babble about every thing finding its proper level by open competition in the market of talents as well as of teas or turnips, every man of sense is ready to avow that something like a monopoly practically exists in many cases. When the Reform Bill, and its supplementary laws, were debated, Sir James Scarlett objected to the proposed payment of five guineas a day for revising barristers, as being so small that no man of any standing would accept the place; yet an army physician puts up with one guinea per diem, and has certainly more than 1-5th of the acquisitions of his more fortunate brother. The principal reason of the difference undoubtedly is, that legislators are frequently barristers, but very rarely physicians; and while they would feel a great repugnance to see the one profession ground down by open competition, are careless of such a result in the other. The same explanation will apply in part to the case before us, to which we may add, that the framers of the Act were riding their Malthusian hobby with great spirit, and were determined (if we may use such a contradiction in terms) not to be fettered in their scheme of pinching economy by any regard to expense.

Better days, however, are approaching; the medical profession has been so long at the bottom of the wheel of fortune, that any turn must be in their favour; and if the example of the practitioners of Bridgwater is followed by others, with the same spirit with which it has been set by them, the voice of reason and of humanity must again be heard.

* Facts connected with the Medical Relief of the Poor in the Bridgwater Union. Bridgwater, 1837. 8vo pp. 28.

+ Ibid, p. 7, note.

The notice of the Board of Guardians was issued on the 22d of May, 1837, and they no doubt expected that the medical men of the neighbourhood would jump at such tit-bits, and probably offer to do the jobs for less than was proposed. How unspeakable, then, must have been their astonishment, when, on the 2d of June, they found their offers very courteously but very decidedly declined by the seven surgeons of the previous year (Messrs. Toogood, King, Ruddock, Tilsley, Addison, Caswell, and Poole,) who, at the same time, declared their readiness to resume their duties on fair and equitable terms. Nay more; as it is said that the essence of a lady's letter is in the postscript, so this one had a stinging supplement in the shape of a declaration from nine other surgeons practising in Bridgwater, who not only concurred in what the writers of the letter had said, but added, that the poor could not be properly attended by competent medical officers, at the salaries offered, without subjecting them to considerable loss. The medical officers were also encouraged in their determination by all the established practitioners of the neighbourhood; but what must have been the bitterest pill for these most parsimonious of guardians to swallow was, that the Poor-law Commissioners, in their Second Annual Report, have themselves stated that the surgeons are the most proper persons to form an estimate of what should be considered a remuneration for their services. Their words, which are quoted in the pamphlet before us, are, "The elements upon which that calculation must be founded are, in themselves, obscure, and are utterly unknown to the persons who are selected for the office of guardians. The medical practitioners themselves cannot fail to be possessed individually of the knowledge necessary for making the calculation."

The would-be economists were now in a sad quandary; the surgeons had discovered that union is strength, for doctors as well as guardians; and the workhouse senate was consequently in the following dilemma. If they yielded, they might expect a fine jobation from the Infallible Three; and they would unquestionably be reproached for their profligate diversion of public money into the overloaded pockets of country surgeons. Again, if they refused to yield, they might expect to hear from their masters that they had been skinning flints with too unwearied a zeal, and would be quietly referred to the passage wherein it is declared that medical practitioners know the value of their services better than the guardians can. We are far from wondering, therefore, that the Board was gravelled by this sensible letter, and returned no answer.

As no answer arrived, the medical officers again wrote to the Board at greater length; and while they declared their readiness to acquiesce in any equitable arrangement, they offered to attend the poor gratuitously in the interim, provided the arrangement was made within a reasonable period.

On the 9th of June the Board sent an answer, stating that they could not treat upon any other terms than those mentioned in the circular, until the 16th, the day fixed for the election of medical officers for the ensuing year.

Accordingly, "on the 16th of June, they offered to take the charge of the districts marked 2, 6, 7, 8, at fourpence a head; No. 5 at threepence three farthings; and the Bridgwater district at threepence, on the gross population of 1832; and the Union House, which is intended to contain three hundred people, at fifty pounds a year*."

On turning to the circular of the

* Facts, &c. p. 12.

Board, we find that No. 2 is the Huntspill district, containing four parishes, with a population of 3001; so that at fourpence a head, the medical officer would receive 50*l.* per annum. Supposing, then, his outlay for drugs to be 4*l.* per annum (a computation certainly under the mark), his daily stipend would be half-a-crown. Number 6 is the North Petherton district, containing five parishes, with a population of 4679. Fourpence a head will amount to 77*l.* 19*s.* 8*d.* per annum; which, after deducting 5*l.* for drugs, will afford a daily income of four shillings. A regal salary! especially as the surgeon would seldom have more than forty or fifty patients on his list, except, indeed, during an epidemic, when his practical tact would be sharpened by the addition of a couple of hundreds.

It is obvious that the terms proposed by the medical officers themselves are very low—injuriously low, indeed, to all parties*. What would be thought of a surveyor, or attorney, who should propose to do a good deal of work for four or five parishes, every day of his life, at the rate of half-a-crown a day? And in what style would men of sense expect the business to be done? This is the result of the excessive competition which has been the bane of our profession, and which can be remedied only by practitioners generally following the example set them by the surgeons of Bridgwater.

The terms, however, were summarily rejected by the Board. Their next step was to *appoint unqualified persons to two of the nine districts*; and while advertising for medical practitioners, in the London and provincial papers, and in the weekly periodicals, the Board

authorized the surgeons who had before taken charge of the vacant districts, to attend the poor at the same rate as they did their own patients!

The Board, previously to these their moon-struck days, had divided the Polden Hill district into two, for the plain reason that it was too large for any one practitioner to manage; but now, having become demented, they appointed one of the unqualified persons to the Middlezoy district, in addition to the one he had already; making altogether ten parishes, and including a much larger space than the district which they had formerly divided into two, on account of its immense extent.

During the three weeks that each case attended was to be charged separately, the relieving officers were directed to be sparing in their orders for medical relief, and the poor were neglected accordingly. The following case, which we abridge from the pamphlet, is a striking commentary on the new Poor-Law; it should be appended to all future editions:—

Charlotte Allen, aged 31, who had been suffering for many years from a disease of the liver, was reported by the medical officer to be in a critical state, and in daily expectation of her delivery. Nevertheless no order was allowed, and she was delivered by a woman, after a difficult labour, on Friday, the 30th of June. She became worse and worse, but still remained unattended, because the relieving officer said “no order must be given, unless in cases of absolute necessity, as it was *very expensive*.” The attendance of the surgeon was at last allowed on the following Wednesday. He found that the poor woman had been attacked by puerperal fever, and, from the severity of the labour and the unskillfulness of the midwife, had suffered a dreadful laceration, and “a prolapsus of the womb; which is not

* They are lower than those recommended to the Guardians, as a guide to their calculations, in the Appendix to the Second Report of the Commissioners. It is there stated, that from fourpence to fivepence a head appears, under ordinary circumstances, to be considered reasonable, by medical gentlemen.—(Facts, &c. p. 25.)

only irremediable, but must render the remainder of her existence miserable to herself and intolerably offensive to those around her."

Four months after her delivery she was still unfit for anything, and could stand upright only a few minutes at a time. In fact the woman is ruined for life — but then the Union has saved TEN SHILLINGS!

Other cases, for which we cannot make room, next follow, in some of which death obviously resulted from the tardiness of the relief afforded.

After the blood of the poor had been thus "coined for drachmas," the day came for making the medical appointments. The admirable Board, which at first had divided the Union into seven districts, and then, finding these too large, had made nine of them, now determined to reduce them to six; thus punishing the poor for their own pitiful proceedings. Only three new candidates came forwards; while five of the medical officers previously employed wrote a letter to the Board, inclosing their bill from Midsummer; and offering either to take a district on the terms they had already proposed (in which case they would give up the amount of their bills, the salary being made to begin from the 24th of June); or to take another one on the terms proposed by the Board in an advertisement dated June 24th.

The Board first appointed Mr. Tilsley (one of the five) to the North Petherton District, with a salary of 75*l.*, (being only 2*l.* 19*s.* 8*d.* less than the amount at 4*d.* a head), and promised at the same time to pay his bill.

They next called on Mr. King, to whom they proposed the following question, which was not put to Mr. Tilsley: "Whether, in the event of the appointment of any non-resident practitioners who offered in consequence of the advertisements, he would hold any professional communication with them?"

He replied, that since the gentlemen had been brought forward to oppose him, *against whom not the slightest complaint had been made*, he must decline doing so; on which he was rejected by a small majority, and one of the new candidates was elected instead. The same question was asked of Mr. Caswell, and the same answer obtained. He, however, obtained his district by a majority of one. The only remaining district was the Cannington, with which the Board had determined to unite the Stowey district, making, altogether, fourteen parishes, and covering an extent of country ten miles long and eight broad!

A stranger was elected for this district in place of Mr. Ruddock, but he immediately resigned: on this, the Board elected Mr. Ruddock, who refused to undertake the care of so enormous a district, and, by a new arrangement, was allowed to divide it with Mr. Poole.

The Board of Guardians thus sorely buffeted, and willing to show of what stuff they were made, determined to conclude by an act of insolvency. Accordingly, on Friday, Oct. 27, a motion was made, and carried by a majority of one, that the medical officers should be offered double the amount of three weeks of the present salaries in lieu of their bills; that is to say, 38*l.* 13*s.* 0*d.* instead of 248*l.*!

"Honour to bankruptcy!" says Mr. Carlyle, in his History of the French Revolution; and his reason for honouring the generally unhonoured is, that bankruptcy has a wonderful knack of hurling all sorts of lies, bubbles, and frauds, into their native nothingness; it is their natural and merited end.

The narrow majority, too, is a good symptom; for, when boards of guardians fall out, says a new reading of an old proverb, honest men come by their own.

Meantime, the medical officers intend to appeal to the law for the recovery of the money due to them; we wish them every success, as their cause is not only that of justice violated in their persons, but the cause of oppressed poverty and neglected sickness.

THE UNIVERSITY OF LONDON.

WE understand that a very stormy discussion took place last Saturday, in the Senate of the University of London, as to whether candidates for degrees in arts should or should not be made to undergo any examination on the subject of religion. The question was at length decided in the affirmative, leaving Messrs. Warburton and Lubbock, together with their followers, in the minority. By this decision the candidate is to be examined on the Gospels, and some of the elementary works on Theology. The degree in arts is made a pre-requisite to that in physic; and it is expected that the University will be ready to commence *dubbing* about May.

ST. GEORGE'S HOSPITAL.

Siranguled Hernia—Division of the Stricture on the outside of the Sac(?)—Lithotomy—Necrosis from Scrofula—Necrosis from Accident.

WILLIAM BELL, an ostler, 46 years of age, was admitted, October 22d, under the care of Mr. Babington, having been subject to inguinal hernia on the left side for many years, which has been partly irreducible, and for which he has worn a truss. On the 17th, five days ago, a fresh portion came down under the truss, producing pain and sickness for the first two days, since which, the sickness has not been much. He had nothing done for the strangulation till yesterday, when ineffectual attempts were made for a considerable time to reduce it; and he was admitted about 12 to-day. He has had no motion since the strangulation, except after some injections yesterday and this morning, containing very little faecal matter.

The hernia is of large size, eight inches

long, with the testis at the bottom; the scrotum red, and slightly oedematous and painful. The tumor is very hard in the neck of the sac, and contains a good deal of fluid below; it is not very tender except in the neck; there is very little tenderness in the abdomen, which is not much distended. Tongue dry and furred; pulse 84, rather sharp; not great anxiety. He was seen by Mr. Hawkins, in Mr. Babington's absence, who thought it right to operate immediately, from the length of time that strangulation had existed, and the hardness and tenderness of the neck of the sac, and being an old and large hernia with a wide ring, it was thought a proper case to try and divide the stricture without opening the sac. An incision was first made down to the tendon of the external oblique, which was cut, but without its allowing the hernia to be lessened by pressure; the cremaster and edge of the deeper muscles were then divided, so as to expose the outer sac, but no more room was thus gained within; and there was not any trace of hardness or prominence to show whereabouts the stricture was situated, the outer surface being every where quite smooth where exposed by the incision of the cremaster. An opening was therefore made into the sac; and on introducing the finger, Mr. Hawkins said he felt a firm band dipping perpendicularly from the sac round the lower part of the neck, which being divided, the intestine was reduced, and the omentum examined; and as a good deal of it was condensed and hardened, and adherent at the lower part, it was left in the sac. Some difficulty was experienced in sewing up the wound, from the great mass of omentum, and from intestine being forced down whenever the man struggled or moved, which he did a good deal.

At five o'clock (the operation having been performed at half-past one) Mr. Hawkins found the pulse sharp, and a little more frequent, with some tenderness round the wound.

V. S. ad $\frac{3}{4}$ xij. Blood a little buffed; not cupped.

R Hydrarg. Chloridi, gr. iij.; Opii, gr. $\frac{1}{4}$. M. 3tis horis.

9 P.M.—Pulse 120, more sharp; more tenderness.

V. S. ad $\frac{3}{4}$ xvi. Blood much buffed, and cupped.

23d, 1 P.M.—Passed a quiet night, having had scarcely any pain since the last bleeding. Pulse 100, softer. No motion.

R Calomel, gr. viij.; Extr. Coloc. Comp. gr. x. M. statim.

10 P.M.—No evacuation; abdomen more

distended, with complaint of flatulency. Pulse 100, soft.

Omit Pil Cal. et Opii, (nearly 1 dr. of Calomel taken.)

R Magnes. Sulphat. ʒij.; Aquæ Menth. Piper. ʒiiss. M. 2dis horis donec alvus respond.

24th, 2 P.M.—Bowels plentifully open three times, with much fecal matter. Pulse 92, soft.

Omit Mist. R Extr. Coloc. Comp. gr. viij. h. s. s. A pint of beef-tea.

25th —Pulse 84, fuller, but soft. Bowels open well; no pain; feels and looks better.—Half pint of porter.

From this time every thing went on well, except that a little cellular texture sloughed at one part of the wound, which united well, however, every where else, and is now (Dec. 3d) nearly well.

This history is instructive, as it shows that in a case such as is usually considered the most fitted for the operation of dividing the stricture, wherever it may be situated, on the outside of the sac, the surgeon has not always a choice, from the stricture being really produced by the inner surface of the sac; and we believe it is by no means always an easy matter to divide the stricture, even when its place is evident, and it is formed by the outer part or cellular texture, from the very firm texture of the parts the result of inflammation. The case is also an interesting one, from its showing the immediate occurrence of severe inflammation from the operation itself; the pulse rising forty beats in a few hours, and the different appearance of the blood in the two bleedings, both showing how the inflammation was occasioned.

On Thursday, November 30th, three operations were performed by Mr. Hawkins.

John Wheeler, æt. 9, admitted November 17th, having been sounded in the country, and a stone felt. Apparently a tolerably healthy boy, but thinner lately. First experienced pain and difficulty in voiding his urine two years ago; passes it now very frequently, with much pain and straining, and chiefly involuntarily. It is said to be sometimes tinged with blood, and to deposit a sediment. Pain referred to the bladder and loins. Prepuce elongated. Bowels open only about once in three days.

He was sounded on the 18th, but no stone felt. He was kept quiet, and took saline and alkaline medicines, with an opiate at night; under which treatment he became much relieved from his symptoms, so as to sleep for several hours, and retain a good deal of water. The urine

was sometimes acid and at other times alkaline; it contained once a little pus, and was always albuminous.

On the 24th he was sounded again, and a calculus distinctly felt. He took some castor-oil the evening before the operation, and had an injection in the morning, by which means the bowels were well opened.

The operation was done with a common scalpel only, and a good deal of time was occupied in the dilatation of the neck of the bladder, from the size of the stone, which was an inch long by three-quarters wide, and was composed apparently of lithic acid, with a good deal of the triple phosphate beautifully crystallized. A short gum catheter was passed through the wound after the child was put in bed, which was withdrawn two days afterwards (on Saturday), and the water passed freely by the wound. Since the operation the boy has slept soundly, which he could not do before; he has had no bad symptom whatever, and appears to be going on quite well.

The second operation of to day (November 30th) was performed on an unfortunate man, 28 years of age, with a pasty complexion, who has not had syphilis to account for his disease. Two years and a half ago, without any evident cause, he was attacked nearly at the same time with caries and necrosis of the metacarpal bones and first phalanges of both thumbs, of the middle finger, and one great toe, with suppurating buboes in both groins, and on one side of the neck, and with a serofulous abscess on the cheek. The middle finger was so diseased as to push the other fingers out of their situation, and make the whole hand nearly useless; this was therefore amputated, with an inch of the metacarpal bone. An incision was then made along the thumb, and almost the whole of the metacarpal bone and first phalanx removed, these bones being quite dead and insulated, and broken into numerous pieces, one of which, however, was an inch and a half long. Mr. Hawkins said that as both thumbs were diseased in a similar manner, it would be a great object to save as much as possible; and that, although the thumb would probably be shortened by the loss of the first phalanx, yet it frequently happened that enough of the periosteum of the metacarpal bone was saved to form a good deal of new bone, and afford a basis for the second phalanx to act upon, with a kind of new joint. He had already removed a good deal of dead bone from the other thumb, which seemed firmer, and very likely to be useful, though he had

more doubt about the one he had just operated on.

The other operation was for necrosis of the tibia, the result of a railroad accident some months previously. Mr. Hawkins had removed seven or eight inches of dead bone about a month ago, but some more remained. A shell of new bone was cut off with a pair of bone-nippers, and about three inches of the inner and posterior portions of the old bone removed.

Mr. Hawkins said there was a long piece of the old bone still remaining, which he felt half inclined to remove, as it was much insulated in several parts within the new shell of bone, and he was afraid it might die from the inflammation of the parts in a bad constitution, though it was evidently alive at the time of the operation.

There has been a good deal of inflammation in both cases, but they are now going on well.

ACCIDENTS ADMITTED AT THE LONDON HOSPITAL.

Mr. ANDREWS, Surgeon.

Mr. ADAMS, Assistant Surgeon.

Nov.	Sex.	Age.	Case.
20.	M.	60	Fracture of the left os ilii.
	M.	10	Abscess in the axilla from a blow.

	M.	60	Contused knee.
25.	M.	56	Injured leg.
	F.	3	Burn.
	F.	5	Scald.
27.	F.	2	Burn.
	M.	39	Sprained ankle.
28.	M.	6	Phymosis from ligature (a).

(a.) This case was an instance of an accident (if I may so call it) of by no means unfrequent occurrence. The little boy had, for sport, tied a piece of thread tightly around his penis, and left it. It had been on five days, and he had said nothing about it until his mother observed a considerable swelling of the penis. He was admitted with the prepuce quite oedematous, and an ulcerated line was found about the middle of the organ, extending around it. He denied having played any tricks with the penis; but it was clear that a ligature must begirt it: a careful inspection soon proved the correctness of the opinion, for at the bottom of the wound a small thread could be felt; this was divided and drawn out. The edges of the wound had begun to cicatrise. The case speedily recovered.

These cases are highly important to attend to, as without much care the ligature may be overlooked, and the result will be the production of a troublesome form of stricture. In cases, therefore, of phymosis, without apparent cause, occurring in boys and children, it is requisite to search carefully for the cause of obstruction to the lymphatic circulation.

In more than one instance the wound has actually cicatrised over the ligature; but there is usually one spot where the thread may be remarked, and this corresponds to the knot. A case of this description was admitted last year, where many surgeons had overlooked this fact, and the swelling of the prepuce remained unnoticed for twelve months. A careful examination, however, brought to view the knot of a ligature, which was cut and drawn out, and the case rapidly recovered.

MR. WAKLEY, M.P., AND MR. S. COOPER.

To the Editor of the Medical Gazette.

SIR,

It is justice to my friend Mr. Wakley, whose personal character has been grossly assailed by Mr. Samuel Cooper, in the last number of your work, I have to intreat the insertion of the accompanying correspondence in the next number of the LONDON MEDICAL GAZETTE.—I have the honour to be, sir,

Your most obedient servant,

W. BURT.

Dudley Grove, Padlington,
Dec. 6, 1837.

MR. WAKLEY, M.P., TO CAPTAIN W. BURT.

Bedford Square,
Monday Morning.

My dear sir,—I have to request as a particular favour, that you will call, without a moment's delay, on Mr. Samuel Cooper, of No. 7, Woburn Place, Bloomsbury, and inquire whether he is the author of an article which is printed at page 390 of the accompanying periodical work.

Should Mr. Cooper acknowledge that he wrote the communication in question, a circumstance which it is difficult to anticipate, your experience and judgment will dictate the course which should be pursued by, my dear sir,

Yours faithfully,
(Signed) THOMAS WAKLEY.

CAPTAIN WM. BURT TO MR. WAKLEY, M.P.

My dear sir,—I received your note this morning at half past 11, and called at the residence of Mr. S. Cooper at half-past 12, and again at 1 o'clock, but I did not succeed in seeing him until half an hour afterwards, when I met him at the door of a Dispensary in Great Russell-street.

Having stated the object of my visit, Mr. Cooper acknowledged himself to be the author of the article which contains the discreditable attack on your private character, but shrank at once from all personal responsibility; and then talked, as might be expected from such a person, of law and damages.

I am, my dear sir,
Yours very faithfully,
W. BURT.

Dudley Grove,
Half-past 4, P.M., Monday.

[We last week omitted a part of Mr. Cooper's communication; so now we do not think it necessary to insert the concluding portion of the letter from Mr. Wakley's friend, wherein after the narrative above given, he proceeds to the expression of his own opinion regarding the conduct of Mr. Cooper.—ED. GAZ.]

LECTURES

ON THE

PHYSIOLOGY AND DISEASES OF THE CHEST,

INCLUDING THE PRINCIPLES OF PHYSICAL
AND GENERAL DIAGNOSIS,

Delivered during the Spring Seasons of
1836 and 1837,

At the Anatomical School, Kinnerton-Street,
near St George's Hospital,

By CHARLES J. B. WILLIAMS, M.D. F.R.S.

Examination of the Chest through the Vital Properties or Functions of its Organs—Analysis of the general Symptoms of Diseases of the Chest—Dyspnoea; its Nature and Value—Frequent Breathing—Feeling of Oppression—Power of Divers, &c.—Professor Faraday's Mode of enabling a Person to hold his Breath—Table of the Causes of Dyspnoea—Cough; its Nature and Causes—Varieties of Cough, and their Causes:—Catarrhal Cough—Hacking Cough—Irritable and Nervous Cough—Convulsive Cough—Whooping Cough—Hooping Cough—Hollow Cough—Varieties, from the state of the Bronchial Secretion, &c.

WE have been occupied in the preceding lectures in considering the physical properties of the chest and its organs, and the manner in which these properties may become signs of the condition of these parts. We have now to examine them through their vital properties, which, combined with certain physical and chemical powers, constitute function. We have already inquired into the elementary vital properties immediately concerned in the function of respiration—sensibility and contractility, to which may be added, the power of secretion; and we then found how closely

these properties are linked together with the chemistry and mechanism of the organs of respiration, so as to constitute their healthy function. Now any excess, defect, or disorder of any of these properties, will be more or less felt throughout the links of this chain, and hence may arise not only derangement of the function of respiration, or *dyspnoea*, but also new phenomena, proceeding from a loss of due balance of the properties, such as *cough*, *expectoration*, and *pain*; and linked as the vital properties are with those of other organs, there may be added disorders of these, in the form of disturbance of the circulation, and its sign the arterial pulse, general fever, disorder of the secretions of the kidneys, liver, and intestines, and of the digestive, nutritive, and sensorial functions. The phenomena arising from these several disordered properties are what are called the *vital or general symptoms* of disease, which we now have to consider in relation to the organs of respiration.

Now it must at once strike you, and I think it will be more apparent as we proceed, that these general symptoms, dependent as they are on such a linking together of many properties, the laws of which are but imperfectly understood, must be far less simple and intelligible than the physical signs; and the variable measure of the vital properties also renders general symptoms far more uncertain than these signs, in their degree, and even in their presence. We cannot with any certainty, as with the physical signs, from a knowledge of the phenomena, and the laws which regulate those phenomena, deduce the condition of the parts which produce them, nor from knowing the condition of parts and physical laws, deduce what phenomena the parts ought to develop. For example, the solids of the body have sensibility, which varies not only in different parts, but in the same parts at different times, and this for reasons which we cannot discover, therefore we cannot calculate on

it. The contractility of moving parts also varies in a similar manner; and we can by no means gain, from the character of their motions, a criterion of their true condition. Instead, therefore, of pursuing the synthetic as well as the analytic method, which we have done with regard to the physical examination of the chest, we shall shortly analyse the chief general symptoms of diseases of the chest, and by that examination endeavour to determine their nature and varieties, and their value in teaching us to discover, to measure, and to treat these diseases.

Dyspnoea, difficult or disturbed breathing, is the most important general symptom of disease of the chest, inasmuch as it implies some interruption to the due performance of some part of the great function of the chest—respiration. Dyspnoea may be caused by circumstances affecting any one or more of the several elements concerned in the function of respiration; viz. the blood in the lungs, the air, the machinery of respiration by which these are brought together, and the nervous system through which the impression which prompts the respiratory act is conveyed from the lungs to the medulla oblongata, and thence to the muscles which move the machinery; in fact, all the causes which in excess produce asphyxia, in slighter degrees occasion dyspnoea. I will presently shew you a table which exemplifies these causes of dyspnoea; but let us now attend to the character of the symptom itself.

When any thing interferes with the sufficient action of the air on the blood, the impression which prompts the act of breathing not being relieved, causes a quicker and fuller repetition of this act, and if the interference still remain, the breathing will continue to be more or less hurried and forced, until the sensation or impression is reduced to the ordinary standard of almost unconsciousness. Now an individual in whom the breathing is hurried may not be sensible that it is accelerated; whilst in another who feels the oppression there may be little appearance of shortness of breath. Again, the feeling of dyspnoea must greatly depend on the condition of the sensorium; for whilst some patients are conscious of the slightest infringement on their respiration, others, particularly in congestive fevers, are brought to the verge of asphyxia without complaining of any oppression. So, too, we are so at times astonished to find, on opening the bodies of the dead, a whole lung diseased, or one side of the chest full of serum, where the patient had not complained at all of dyspnoea; while, in other cases, a much smaller lesion of the organs has been attended with the most distressing orthopnoea. It is, however, rather to the sensation of breathlessness than to merely

accelerated breathing, that the word dyspnoea is generally attached: for translating it as difficult breathing, this expression can be hardly applied when the difficulty is overcome by accelerated movements, of which the patient may not be conscious. But we will not waste our time on words; but advert to frequency of breathing, as well as the feeling of dyspnoea.

The number of respirations in a healthy adult male at rest generally ranges about twenty in a minute. It is more in children and in females, and it becomes increased in all ages, not merely from affections of the lungs or connected organs, but also from general weakness or depressing causes, which, diminishing the strength of the muscles of respiration, oblige them to make up by the frequency of their contractions what is wanting in their energy. Probably there are some nervous conditions of the system also, in which the breathing becomes accelerated, from what Cullen called *mobility*, a greater readiness to move than power to complete the motions. I have seen the breathing hurried in some cases of hysteria, without the patient being conscious of it, and without either real weakness or pectoral disease to account for it. These cases are of no consequence in themselves, but should be known, that they may be separated from those of true dyspnoea. In many other cases, especially those, I believe, where the nervous system is affected, the breathing is not accelerated, but suspirious, a sigh or deep breath being taken from time to time; yet the patient is often not conscious of any oppression or unusual effort. This may be called irregular breathing, and there are several other varieties, which we have not time to consider in detail. The rhythm in breathing probably depends entirely on the chain of influences which we before described as concerned in the act, and not on any peculiar periodicity, such as that which seems to reside in the heart; and therefore irregular breathing must depend on a change in one or more of the links in that chain.

The feeling of dyspnoea is one of a very peculiar and distressing character. Even when slight in degree, its permanent oppressive influence is very wearing; and when severe, it causes the most horrible suffering, with such a feeling of impending death, that the most courageous are often unmanned by it. The constrained postures of the patient, the anxious or even desperate expression of his countenance, the painful straining of all the muscles that can in any way, however distantly, assist in the respiratory movements, bespeak the intensity of the feeling, which I have heard several people say is far worse than the most acute pain. It is worthy of re-

mark, however, that this feeling is experienced in its severest degrees only by those in whom the dyspnoea comes on rather suddenly, especially when the sensibility is entire, and the lungs are not diseased, as in obstructions in the trachea or large bronchi, spasm or swelling of the glottis, and spasmodic asthma. In these cases the sensibility is not gradually blunted by the circulation of imperfectly oxygenated blood; nor has the activity of the functions, which require arterial blood, been lowered by previous depressing causes. Opium, belladonna, camphor, and other narcotics, will sometimes relieve the symptom of dyspnoea, not only by deadening the sensibility, but also by diminishing the activity of those functions and secretions which require oxygenated blood, and therefore a free supply of air. If we could temporarily produce a state approaching to the torpor of hibernating animals, we might diminish the bad effects, as well as the painful feeling of dyspnoea; and I believe that such a state is actually induced in those who are habitually asthmatic, in whom all the functions are brought to a lower standard, and who thus suffer with impunity such an encroachment on the function of respiration as would be fatal to an individual of a common standard.

The feeling of want of breath has been used as a means of testing the condition of the respiratory organs. A person whose respiration is free and unembarrassed, can hold his breath longer than one whose lungs are diseased. Some one, I think Dr. Lyons, has proposed to measure the condition of a patient's lungs by the time which he can continue without taking breath after a full inspiration, and to insure accuracy, the patient is desired to count numbers during this time. A healthy person with a good chest can continue counting for forty-five seconds without taking breath, whilst those with diseased lungs often cannot keep on for twenty seconds. The same objection may be made to this test that we made to the measuring of the exhaled air proposed by Abernethy; that it is a test as much for the strength of the muscles of respiration as for the condition of the lungs. Besides, both the feeling of want of breath, and the power of augmenting the respiratory movements, vary considerably in different healthy subjects. It is well known that divers acquire the power of remaining under water for two or three minutes (it has been said more) without taking breath. In diving animals there is a structural provision to enable them to continue some time without air. The chief venous trunks are very tortuous, and admit of dilatation, so that the venous blood can accumulate in them, instead of distending and embar-

assing the right cavities of the heart and the lungs. Perhaps some change of this kind may be somewhat produced in divers, by the often repeated practice of holding the breath. Professor Faraday has described another mode by which a person may be enabled to hold his breath for a minute and a half, which is double the time usually practicable. This is by making in succession five or six full and forcible inspirations, which seem to so completely change the air in the lungs, that there is left in them a stock of pure air capable of lasting during that time. The knowledge of this fact may be useful, if ever you should want to hold your breath for a time in going into the suffocating atmosphere of a sewer, a mine, a house on fire, or the like, or in diving.

Dyspnoea is often a symptom demanding great attention in diseases of the lungs; but it must be studied in conjunction with the other general symptoms and the physical signs, for in itself it is most vague and inconclusive. You will perceive this on inspecting this tabular view [see next page] of the causes of dyspnoea, which is founded on the physiology of respiration, as described at the beginning of this course. You will find it worth studying, not only in shewing the varied nature and origin of the symptom, but also in contrast with our tables of the physical signs, the causes of which are much less varied, and far more appreciable. But when through the means of the physical and other general symptoms, it has been made out on what cause the dyspnoea depends, then this symptom often becomes a valuable measure of the increase or diminution of the disease, and a useful guide of our practice.

Let us now attend to another symptom, which is even more common in diseases of the chest than dyspnoea is—I mean, the *cough*. The act of coughing consists in one or more abrupt and forcible expirations, accompanied by a contraction of the glottis, trachea, and upper bronchial tubes. The expirations being more complete than usual, especially when there are several of them, are followed by a deep forcible inspiration, the force of which is shown by the loud respiratory murmur, which, by the ear applied to the chest, may be heard to accompany it. The muscles chiefly concerned in the act of coughing are the abdominal muscles and intercostals, as I explained in speaking of the physiology of respiration.

Let us see what is the essential cause of this act: you know that the common cause of cough is phlegm or some other matter irritating the air-passages, and the object or final cause of the cough is to expel or expectorate this matter. Well,

PROXIMATE CAUSES OF DYSPNOEA, OR DIFFICULT BREATHING.

1. BY IMPEDING THE ACCESS OF PURE AIR TO THE LUNGS.

a. *Mechanical.*

Rigidity of parts of the respiratory machine	e. g.	Ossification of cartilages; induration of the pleura; rickety distortions, Tumors or dropsies of the abdomen.
Pressure on ditto	e. g.	{ Effusions in, swellings of, tumors pressing on, the air-tubes ;
Obstructions of the air-tubes.....	e. g.	{ Spasm of the glottis ; spasm of the bronchi.

Compression of the lungs	e. g.	Effusions or tumors in pleural sac
--------------------------------	-------	--

Engorgement.

Alterations in the tissue of the lungs	e. g.	{ Effusions
		{ { Oedema,
		{ { Hepatisation,
		{ { Tubercle, &c.
		{ { Emphysema,
		{ { Dilated bronchi,
		{ { Vomica, &c.
		{ Altered structure.....

b. <i>Chemical.</i>		
Deficiency of oxygen in the air	e. g.	Mephitic gases; rarified air.

c. *Vital.*

Pain of parts moved in respiration	e. g.	Pleurodyne; pleuritis; peritonitis, &c.
Paralysis of muscles of respiration	e. g.	{ Injuries of the spinal marrow in the neck, &c.
Weakness of ditto	e. g.	{ Paralysis of the bronchi (?)
Spasm of ditto.....	e. g.	{ Excessive prostration, from ataxic fevers, &c.
	e. g.	{ Tetanus; spasmodic asthma, &c.

2. BY THE STATE OF THE BLOOD.

a. *Mechanical.*

Obstruction to the passage of the blood.	e. g.	Diseases of the heart and great vessels; tumors pressing on them.
--	-------	---

b. *Chemical.*

An excessively venous state	e. g.	Violent exertion; idiopathic dyspnoea (?)
Deficiency of red particles.....	e. g.	Anæmia; chlorosis.

3. BY THE NERVOUS RELATIONS OF RESPIRATION.

Excessive sensibility of the par vagum	e. g.	Hysterie dyspnoea; cerebral fevers; neuralgia (?)
Defective ditto.....	e. g.	Coma; narcotism, &c. (breathing slow).

I believe we may fairly say that the proximate cause of cough is always some irritation, either direct or by sympathy, of the sentient parts of the air-tube, or of the nerves which render them sentient. Some parts of the bronchial membrane are much more sensitive than others; that lining the glottis and larynx is excessively so, and the least irritation of it is enough to excite coughing. That of the trachea and large bronchi is less, for foreign bodies have been known to lodge in them for some time without causing any coughing, so that some have supposed that they have nothing to do with the production of this symptom; but when the sensibility of these parts is increased by inflammation or nervous excitement, any thing irritating them will also excite coughing. You can easily see why the sensibility of the air-tubes should be greatest at their entrance; it is the *door-keeper*, placed there to exclude, or, by calling other forces to its aid, to expel any thing improper which may intrude. But the other parts of the tubes have also a preserving sensibility, which may bear a little, but is soon roused into activity by continued irritation. We find the parallel of this in the alimentary canal in the natural state. The sensibility that excites the action of vomiting is peculiar to the fauces at one end of the tube; and that which induces the striving of defæcation resides chiefly in the termination of the rectum at the other end; but uncommon degrees of irritation, or an exalted sensibility, will occasion the same actions to be excited by impressions on other parts that are usually insensible: hence arise the vomiting caused by an over-irritated or inflamed stomach or duodenum, and the tenesmus and purging excited by a similar state of the colon. We shall see this more fully on considering the various causes of cough.

As other irritations, cough may be excited either by an unusual irritant acting on the tubes in their natural state, or by the ordinary circumstances, which, although not usually irritating, yet become so by the exalted irritability of the tubes; or, as is the more common case, by a combination of these causes. You have an example of cough excited simply by an unusual irritant, when a portion of food or of bronchial mucus lodges on the membranes of the glottis; and an irritant may act by sympathy as well as by direct application, as when you excite coughing by introducing a probe pretty far into your ear. The cause by increased irritability is exemplified in the cough of early bronchitis and nervous asthma, which the mere inhalation of air is sufficient to excite. You have both an unusual irritant, and increased irritability in the secreting stages of bronchitis, and other

affections, where an unusual quantity, and sometimes an irritating kind, of mucus is poured out on an over-sensitive membrane. This more complex cause of cough is frequently induced by the continuance of the other causes; thus, the continued application of an irritant will develop an increased sensibility, and increased sensibility and irritation will be followed by inflammatory excitement and the secretion of matter, the quantity and quality of which add to the irritation. Thus you see how the physiological causes of cough become identified with the pathology of bronchitis, or inflammation of the membrane of the air-tubes; and in common parlance, you know, a bronchial inflammation is called a *cough*, this being the most prominent symptom. But although this inflammatory condition is often developed by the continuance of causes which produce cough, yet it is not necessarily so, and there may be irritation or increased sensibility, or both, enough to cause cough, and which may yet be short of the degree or the conditions requisite to produce inflammation.

I have said that the irritation which causes cough may not be applied to the bronchial membrane itself, but may be exerted from a part more or less distant. Thus you may have a cough excited by tubercles in the parenchyma of the lungs, by inflammations or irritations of the pleura, peritoneum, stomach, liver, and so forth; and although we may conjecture that these irritations are conveyed through the nervous branches which connect these several organs and the air tubes with one common sensitive centre, yet we cannot explain why they should be sometimes conveyed, and at others not; for although cough does frequently accompany the pathological conditions to which I have just adverted, yet it is very certain that you may often have irritations and inflammations of the stomach, liver, peritoneum, &c., sometimes even of the pleura and pulmonary parenchyma, without any cough whatever. I have heard some one try to explain these discrepancies, by assuming that there must be bronchitis present to produce cough, and that when these several distant irritations do not excite bronchitis, they are unaccompanied by cough; but this view increases the difficulty instead of diminishing it, for it leaves unexplained the reason why this supposed bronchitis should occur in some cases and not in others; and bronchitis, although including cough, is more than cough, and needs something more to produce it. We may conjecture about local weaknesses, constitutional peculiarities, and irregular sensibilities, as causes of these differences, and this is all that we can do towards explaining them, but this is not what an

explanation ought to be; this is referring phenomena not to known general properties, and the laws which govern them, but to individual peculiarities, and undefined influences, the laws of which are not known. These considerations furnish you with another proof of the uncertainty of general symptoms, as means of diagnosis. Still, when cough does occur, and its cause has been made out by the aid of other signs, it deserves attention, not only as a symptom, but as a morbid action of a distressing and hurtful kind, which sometimes may require remedies expressly to relieve it. This illustrates what I have before told you, that general symptoms, although much less constant and instructive than physical signs, with regard to the diagnosis of organic lesions, yet, when positive, often tell us more of those general conditions of the system, which become our guides in the employment of remedies.

Under this impression, I think that we shall do well to examine some of the varieties of cough which present themselves in different cases, and to trace the connexion between their characters, and the variations in elements that constitute them. Of course the study of a symptom in any individual case must be conjoined with a proper survey of its functional or organic cause; but as we have also (sometimes only) to treat the symptom, it is highly useful to study its varieties, and thus to render it more practically instructive.

The cough may vary according to—

1. The irritant exciting it.
2. The sensibility feeling the irritation.
3. The movements thereby excited, which consist of, *a*, the contraction of the muscles of respiration, and *b*, the contraction of the air tubes.
4. The condition of the bronchial membrane and its secretion.

Under these heads, we shall meet with varieties of cough with which, I dare say, you are all familiar.

1. When other things are equal, the violence of a cough will be in proportion to the degree of irritation that excites it. For example, a healthy person whilst eating or drinking, incautiously suffers some food to enter the glottis; the cough thereby excited will be more severe with wine or any thing peppered, than with water or any bland food. So in the early stages of catarrh, although the sensibility of the membrane is increased, yet the thin saline-tasted secretion also acts as an unusual irritant upon it, and keeps up a short teasing, tickling cough, with continued attempts to clear the throat. When the irritation is more moderate, but irremovable, like that occasioned by incipient tubercles in the pulmonary tissue, the

cough will generally be of that slight *hacking* kind, with little or no expectoration, that is so well known as one of the first symptoms of pulmonary consumption. The irritant here remaining the same, the circumstances which increase this cough are those that augment the sensibility of the lung and air-tubes; such as a quickened state of the circulation from exertion, heated rooms, or during the assimilation of stimulating food.

2. We have already adverted to increased sensibility as being concerned in the cough of recent bronchitis or bronchial irritation. It becomes, however, more developed when the cough has lasted several hours, and instead of being short and tickling only, it comes on in more violent and prolonged fits, which are quite irresistible, and often accompanied by a feeling of soreness. The heightened sensibility of the air-tubes is further manifested by the readiness with which breathing air at all cold, or swallowing any thing at all irritating, will excite cough. We have before remarked how this increased irritability of the inflamed air-tubes is commonly joined with the augmented irritation of their secretion; but we do sometimes meet with cases in which the increased sensibility is purely nervous, unaccompanied by any secretion; and the cough is brought on by the slightest cold or irritating matter in the air. Even strong odours will sometimes cause it. These nervous coughs are to be treated chiefly by various remedies which diminish the sensibility of the nervous system, such as narcotics, or sometimes by those which excite stronger impressions in other parts, such as epispastics, and the application of heat.

3. Besides the sensibility of the bronchial membrane, another property connected with the nerves, muscular mobility, may be the source of some varieties of cough. We have no time now to examine the circumstances under which a change of proportionate relation takes place between the action of the motory nerves in general, and the impressions which excite them. It is sufficient for us that the fact is well known, that in certain conditions or states of the system, an ordinary impression will excite inordinate motions; while in others the motions resulting from similar impressions will be imperfect, and below the natural amount. It is thus also with the motions of muscles concerned in coughing. You may have them excessively mobile, so that the least irritation will set them agoing; and like a clock without its pendulum, they continue their impetuous motions, until their strength has fairly run out. This is the *convulsive cough*, which we meet with in some hysterical and nervous subjects, and its convulsive character is the more evident from the fact that it

sometimes alternates with chorca or convulsive affections of other sets of muscles. The same uncontrollable character is, however, often communicated by a nervous temperament or peculiar nervous affections, to coughs arising from common causes, which thus shake and exhaust the patient in an unusual degree, and require appropriate modifications of treatment to subdue them. *Hooping-cough* in its after-stages is of this kind, and from my experience I should say that the shaking uncontrollable nature of the cough is more characteristic of pertussis than the hooping, which is not always present, especially in adults. This leads me to consider on what hooping depends, and here again you will find the use of our physiological divisions which explain some other varieties of cough that are sometimes met with.

In considering the physiology of respiration, we were led to believe that the act of expiration is aided by the contraction of the circular fibres of the air-tubes. In the forcible expirations which constitute ordinary coughing, there is also a simultaneous contraction of the air-tubes, and especially of the aperture of the glottis, through which the air is driven with the greatest force, in order to expel any irritating matter. Now the contraction of these tubes may be excessive, defective, or irregular, and this will occasion other varieties of cough. When their contraction is excessive, being also generally irregular, they give the *whizzing* character to the cough, so remarkable in asthmatic subjects. I do not mean to say that a whizzing cough always depends on contraction of the circular fibres, for other constrictions of the bronchi will also cause it; but if you listen to the chest of a nervous asthmatic, you may often hear, in the forcible expirations of a fit of coughing, sibilant and sonorous rhonchi, which are too transient to be produced by the thickening or secretion of the tubes. Where the irritability of the bronchi is great, their contraction may not, as usual, cease during the act of inspiration; and it is this spasmodic constriction, affecting particularly the upper part of the air-tube during the forcible inspiration which succeeds to coughing, that causes the *hooping* sound. This state of things happens chiefly in the irritable frames of children when affected with convulsive cough, and the violence and repetition of the expiratory efforts of this cough occasion the back draught to be the more forcible, sonorous, and prolonged. If you apply your ears to the chest of a child during a fit of hooping-cough, you will be surprised to find how little sound you can hear there with all these noisy external efforts: in fact, the continued constriction of the bronchial tubes permits very little

motion of air into and out of the tissue of the lungs. In the convulsive cough of adults, again, in which there is no hooping, the respiratory murmur of the long inspiration, or back draught, is pretty loud, whilst the succession of coughs here also consists more of external than of internal movement. In all these kinds of cough, antispasmodics will often give more relief than any other class of remedies.

But we may have an opposite condition of the circular fibres of the bronchi, a weakness or deficiency of action, a paralysis, so that they do not contract as usual during the expiratory efforts of coughing. This constitutes the *hollow* or *barking* cough which we sometimes hear in chronic bronchitis, and now and then in febrile and nervous affections. This cough is, as we shall presently find, accompanied with a difficulty of expectoration; hence it is sometimes very distressing, and particularly so when, as it occasionally happens, it is combined with a mobility of the external muscles of respiration, rendering the cough convulsive and paroxysmal. The tearing and exhausting fits of this kind of cough are sometimes quite agonizing; and we may judge from the bloated, congested appearance of the lips and face, how much these fits impede the respiration and circulation, and how much they may thus tend to increase and perpetuate the diseased condition of the bronchial tubes. In some such cases, I have seen the terebinthinaeous medicines, with external counter-irritation and occasional emetics, give most relief; but the treatment will depend on various circumstances, which I cannot enter into at present.

4. Besides the sensitive and motory apparatus concerned in the act of coughing, we have the secretion of the air-tubes, which may also by its qualities modify the character of the cough. According to whether this secretion is present or not, the cough may be humid or dry; and according to the relation of the qualities of this secretion to the powers of expectoration, the cough may be loose or tight; and these varieties may be combined with the other species of cough, as those may with each other; and thus are produced the endless host of different kinds of cough that we meet with in practice. Without pretending to affirm that you will always be able to classify these by the division that I have now pointed out, I can assure you that I have often found this analysis useful in drawing attention to the predominant changes of vital property, as manifested by this symptom, and in thus distinguishing cases which require different modes of treatment*.

* *Erratum.*—In Lect. VII. p. 276, line 12, 1st col. for “distinct” read “distant.”

ON THE COMPOSITION AND ABSORPTION OF PUS.

By M. BONNET,

Surgeon to the Hôtel-Dieu, at Lyons.

[Continued from p. 413.]

SECT. III.—*Differences of Composition in the several varieties of Pus.*

THE varieties of pus whose differences I have examined, are the creamy, the serous, the tuberculous, the mucous, and also pus mixed with milk.

Concentrated sulphuric acid poured upon pus in a quantity sufficient to dissolve it, produces a reddish tint, which varies extremely in purity and intensity. This reaction, which Berzelius says is constant, engrossed my attention in my first researches into the nature of pus; I wanted to know the reason of its existence and its varieties. I had then just repeated the experiments of M. Raspail upon albumen, and had observed the fine red colour produced by dissolving sugar in sulphuric acid, and pouring it upon albumen. Hence I conjectured that the reason that sulphuric acid produces the same change of colour in pus is, that the latter contains sugar as well as albumen. I was confirmed in my supposition by the sweetish taste which all authors attribute to pus, and which many patients perceive in the sputa containing it, and by the authority of John Hunter, who, in treating of pus, asks if there is no sugar mixed with it.

This supposition, however, has not been confirmed by analysis. Had it been correct, it would have been sufficient, in order to find the sugar, to boil pus in water, and, after filtering, to evaporate the aqueous solution. The extract of this solution would be syrupy and sweet, and by repose would crystallize like the sugar of diabetes; far from this, it is salt, and smells like the juice of meat, and the crystals formed in it are those of the hydrochlorates of soda, potash, and ammonia. These experiments, which I have repeated again and again, both upon pus and upon purulent sputa, which the patients said were sweet, leave no doubt as to the slender foundation of the supposition by which I explained the reddish colour that sulphuric acid gives to some kinds of pus. I then recollected, still following the experiments of M. Raspail, that sulphuric acid gives a red colour, not only to mixtures of albumen and sugar, but also to those of albumen and fat, which made me necessarily believe that pus owed its property of being reddened by sulphuric acid to a

mixture of this kind. The question was no longer doubtful when I had remarked that the fatty matters of pus dissolved in alcohol, and obtained in a separate state by the evaporation of the solvent, took a very fine purplish tint from sulphuric acid; an effect which inclined me to think, that the greater the proportion of these substances in pus, the more intense would be the colour given by sulphuric acid. I verified this supposition by the following experiment:—

Having dried some pus in a water-bath, I exposed its extract several times to the action of boiling alcohol. After each solution, the extract of pus, which before became of a bright red from the influence of the sulphuric acid, took less and less colour from this re-agent, in proportion as the alcohol deprived it more and more of its fatty matters; and when they had been completely removed, the undissolved part was no longer reddened by the acid. I restored this property by mixing it with the fat which the alcohol had taken up. The more fatty matter there was, the more decided was the red tint.

After these preliminary observations, I return to the differential characters of the several varieties of pus.

(a.) *Creamy and serous pus.*—Creamy pus, obtained from hot abscesses, when mixed with sulphuric acid (especially if we stir it and then wait a little), takes a more intense reddish tint than the serous pus derived from cold abscesses. The tint is finer, and the difference equally great, if, instead of adding the acid to these kinds of pus in their natural state, it is poured upon their powdered extracts—a proof that the difference in the intensity of the colour does not depend only on the greater proportion of water in the serous pus, but on the presence of certain elements which remain in the extract. Now these elements are the fatty matters. They seem to me more abundant in creamy pus than in any other; and it is by the greater proportion of these fatty matters that I explain all the properties which distinguish it.

I have said above, that the fatty matters of pus, when mixed with water, give it a milky appearance, and form a real emulsion, which may be compared to almond mixture. It is well known that emulsions hold insoluble substances in a state of suspension, and do not allow them to be precipitated, and in medicine advantage is daily taken of this property, by giving insoluble substances suspended in lozocks. Let it be admitted, then (as analysis has shewn me), that creamy pus contains more emulsive fatty matter than serous pus, and it will be understood why creamy pus does not separate, by standing,

into serum and clot, a separation which one sometimes sees in serous pus—why, in a word, its undissolved parts remain constantly suspended.

If the reader recollects what I have said of the property which these fatty matters have of forming emulsions not coagulable by heat, he will understand a fact which I have often observed, namely, that if creamy pus is boiled, and then filtered after the coagulation of its albumen, the solution which filters through is turbid and milky, and can neither be cleared by acids nor by boiling again. Now this property of affording a milky fluid, even after boiling, belongs to creamy pus alone. It also depends on the proportion of these emulsive fatty matters being greater in it than in other kinds of pus.

Observe, moreover, that this pus belongs to strong patients, and to acute inflammations, which produce a rapid wasting away; while serous pus is found in debilitated persons, and in inflammations which, having lasted a long time, have already attenuated the patient, and now waste him away but slowly: in short, that the first is found in patients who are losing a good deal of fat; and the second, in those who have but little to lose.

Thus chemical analysis, physical properties, and the phenomena observed during disease, all unite in showing that the difference between creamy and serous pus essentially depends upon the greater proportion of fatty matters in the former. The latter, moreover, is more watery, as every author has observed, and as appears from the most cursory inspection.

(b.) *On mucous pus.*—Pus, of a mucous appearance, may be contained in cold abscesses, or secreted by inflamed mucous membranes.

Whether from mucous pus being but rarely contained in cold abscesses, or whether from my attention not being directed to it, I have met with it but once. I punctured a perfectly circumscribed cold abscess, below the right scapula, from which a scrofulous patient, aged 21, had been suffering four or five months; the pus which flowed out was less white and less opaque than serous pus; and it had that semi-transparent tint, that glutinousness, and that disposition to form threads, which we find in mucus. Analysis shewed that it contained the immediate principles common to all kinds of pus. It contained the fatty matters in a scarcely appreciable quantity, was not reddened by sulphuric acid, and after boiling, afforded a perfectly limpid aqueous solution. In its crystallized salts there was very little hydrochlorate of soda, and much hydrochlorate of ammonia. As the appearance of mucus

can be given to any pus by shaking it with a concentrated solution of hydrochlorate of ammonia, I first thought that mucous pus owed its physical properties to the large quantity of hydrochlorate of ammonia which it contained; but having since observed a similar composition in pus proceeding from tubercles on the vertebral column, and in the pus of large cold abscesses, I began to think that the preponderance of this salt belonged peculiarly to chronic suppuration, and debilitated patients. This, however, is a conjecture which requires to be confirmed by new researches.

The mucous pus secreted by mucous membranes has very much engrossed the attention of physicians. Many of them have thought it an important problem to ascertain the distinction between pus and mucus, and to determine when the former is mixed with the latter. To decide these questions, a multitude of empirical experiments have been made: pus and pure mucus have alternately been mixed with water, with solution of potash, or of hydrochlorate of ammonia, &c., on the supposition that some reaction would at last be found to distinguish one from the other. This was a consequence of the erroneous supposition I have already pointed out, that problems in animal chemistry could be resolved by testing such complex products as pus and mucus. To distinguish them it would be necessary to learn to know them when separated, and therefore it would be necessary to analyze them, and reduce them to their immediate principles*. Examining in this way the sputa of chronic pulmonary catarrh, I found that they contained, as pus and blood do, water, albumen, the aqueous and alcoholic extracts of meat, earthy salts, the hydrochlorates of soda and of ammonia, fatty matters forming an emulsion with water, and, lastly, a product insoluble in cold water, hot water, and alcohol. (Most of these substances have been pointed out by Berzelius in the mucus of the nose: vol. viii., p. 463.)

Thus, finding the same immediate principles in pus and in mucus, I concluded that these products probably differ by some immediate principles being more abundant in one than the other; and I was the more inclined to this supposition when I considered, first, that the pus of an abscess

* The best method of distinguishing pus from mucus is that given by Dr. Young. A minute quantity of the fluid to be examined is to be put between two small pieces of plate glass; the glass is then to be held close to the eye, and we are to look at a distant candle, with a dark object behind it: if the fluid be pus, coloured rings will be seen around it; but not, if it be mucus. (Med. Liter. 2nd Edit., p. 574.)—Translator.

may have all the exterior characters of mucus, as in the case above mentioned, and secondly, that we are able to give any kind of pus that semi-transparency, that disposition to form threads, and that adherence of its parts, which seem peculiar to mucus, by mixing and stirring it with a saturated solution of hydrochlorate of ammonia; that is to say, by increasing the proportion of one of its constituents.

It is well known that, at the end of acute pulmonary catarrhs, and during the course of chronic catarrhs (whether they depend on tubercles or not), the sputa often take on a purulent character; this change has no other origin than the more abundant secretion of the emulsive fatty matter, which, even in health, forms a part of the secretion of all the mucous membranes. As it is this same emulsive fatty matter which gives pus its opacity and its yellowish white colour, it is said in such cases that it is pus mixed with mucus; whereas it is merely, as we have seen, an immediate principle common to both, of which the secretion has been augmented in the catarrhal product.

(c.) *On tubercular pus.*—I have nothing to add to what I have said of this pus in two parts of this memoir. As I have already observed, the clots found in it are insoluble in water, in alcohol, and in æther, and cannot be shewn to be different from fibrine by chemical analysis. Its immediate principles are those which exist in every kind of pus. I have made mention of the small proportion of its fatty matter, and of the predominance of the hydrochlorate of ammonia among the salts which are found in the crystals of its aqueous decoction, when placed under the microscope.

(d.) *On pus mixed with milk.*—I have treated of this pus in a memoir on *Fistula Lactea*, inserted in the *Archives de Médecine* for 1836. I might add several cases to those I have already made known, but I reserve them for a new publication. I hope that I shall be able to call attention to ulceration of the lactiferous ducts, a disease so frequent, and so completely neglected, and which can be rationally treated only by being understood.

Here end my observations on the varieties of pus which have not been in contact with the atmosphere; they all combine to demonstrate, that these varieties depend on a difference in proportion between the immediate principles which are common to every kind of pus, and that no kind of pus contains any peculiar principle not to be found in the others. I was long imbued with the common error on this point, and believed in the existence of a tubercular, a purulent matter, and so on; but chemical analysis undeceived me,

and if I continue to publish the results of my researches into these morbid secretions, it will be seen that all these products, so different in appearance, have this in common, that their immediate principles are found in the blood, and that their differences are in the proportion of these principles, their fitness for organization, and the more or less advanced degree of this organization. It will be shewn that, though in animal analysis one may look for albumen, for hydrochlorate of ammonia, or for emulsive fatty matters, we cannot look for pus or tubercle; and perhaps I shall thus contribute to fix, more accurately than has hitherto been done, the point to which the researches of pathological chemistry should be directed, and also contribute to shew the relations of various lesions, their analogies, and their differences.

SECT. IV.—*On the Changes which Pus undergoes when it is in contact with the atmosphere, and putrefies.*

Before treating of the changes which pus undergoes in putrefaction, it is necessary to demonstrate the existence of sulphur in it, and to dwell upon some of the re-actions produced in it by potash, ammonia, and sulphuric acid.

A very simple experiment shews the presence of sulphur in pus, and, in general, in all albuminous fluids. Boil some pus with potash or soda, and then expose test-papers to the vapour which arises from it. You will find that the salts of lead, mercury, iron, &c. will be slightly blackened by the action of the vapour; the salts of antimony will become of a brick-red; the white oxide of arsenic, yellow; in short, that they will take the several tints that sulphuretted hydrogen communicates to them. These effects will be very perceptible if you pour a few drops of sulphuric acid on the pus heated with potash. By the action of the acid thick vapours will be disengaged, which will almost instantly produce upon the test-papers the tints which are characteristic of sulphuretted hydrogen. (To make the experiment succeed well, the neck of the phial should be stepped up by the test-paper.)

It may be presumed that the sulphuretted hydrogen which is formed in the decomposition of pus by potash, combines with the alkali, and forms a hydrosulphate of potash. It seems to me probable, that the decomposition of the pus also produces ammonia, and that a part of the sulphuretted hydrogen is volatilized with it. However, this is merely an accessory circumstance; the fundamental point is the formation of a great quantity of sulphuretted hydrogen, which shews how

considerable is the proportion of sulphur in pus, and, in general, in all albuminous liquids; for I have obtained the same results by acting upon the albumen of the white of egg, upon the serum of the blood, upon dropsical serum, and (which surprised me considerably) upon milk.

When pus is boiled with ammonia, a hydrosulphate of ammonia is formed, which being volatile, rises with the steam of the water; and without the addition of sulphuric acid, this vapour easily acts like sulphuretted hydrogen upon the solutions of lead, mercury, arsenic, and antimony. This experiment, like the first one, shews the presence of sulphur in pus; it shews, in addition, that this sulphur is capable of combining with hydrogen under the influence of ammonia—a fact important to be known in order to comprehend the phenomena of the putrefaction of pus.

I wished to know whether sulphuric acid, when poured upon pus which has not been in contact with the atmosphere, or upon blood, or white of egg, would disengage sulphuretted hydrogen. My experiments produced only doubtful results. Nevertheless, a faint black tint upon the papers dipped in solutions of lead, and a reddish one on those dipped in tartar emetic, gave me reason to suspect the disengagement of a little hydrosulphuric acid.

These premises being laid down, we see that pus containing sulphur, and, like all animal substances, containing hydrogen and azote, has all the elements necessary for the formation of ammonia and sulphuretted hydrogen; very active poisons, which by their combination produce the hydrosulphate of ammonia, a poison not less dangerous.

Now the presence of hydro-sulphate of ammonia with excess of the alkali in putrefied pus, is precisely the point which distinguishes it from pus drawn from an abscess and not exposed to the atmosphere.

Fetid pus is alkaline; and this alkalinity is found even in its vapour, as may be ascertained by placing it in a phial, heating it slightly, if requisite, and then exposing to its vapour turmeric paper or litmus reddened by an acid: the changes of colour which the papers undergo are those which alkalies produce; and as these changes gradually disappear when the paper is exposed to the atmosphere, it is clear that they are owing to ammonia. We have a new proof of the presence of this gas, if we expose a glass rod, dipped in hydrochloric acid, to the surface of the sore which gives forth the fetid pus; the white vapours which this acid disengages become thicker if they were still rising, or

re-appear if they were no longer visible, as soon as the rod is brought near the sore. As to sulphuretted hydrogen, it is easily recognized in fetid pus by placing the pus in a phial, and exposing to its vapour papers dipped in solutions of lead, mercury, or antimony. If putrefaction is far advanced, if the pus issues from a sore or abscess where the cellular tissue is gangrenous, it will at its ordinary temperature give these solutions the black, reddish, and yellow tints, which indicate a disengagement of sulphuretted hydrogen. If the fetor is not so strong, the temperature must be raised; and, in some cases, I have been obliged to add sulphuric acid; but then, unless the development of vapour is very considerable, we cannot be sure that the sulphuretted hydrogen exists ready formed in the pus, as sulphuric acid produces a little with the blood of the healthiest persons.

There is a result which is often observed in surgical wards, and which shows the formation of sulphuretted hydrogen in fetid pus; this is the blackening of the diachylon plaster and lead wash in contact with the pus. This arises from the formation of the sulphuret of lead at the expense of the sulphuretted hydrogen contained in the pus, and of the lead which enters into the composition of the diachylon and the wash; for whenever this change of colour takes place, the presence of sulphuretted hydrogen may be ascertained by the means which I have indicated above.

Many surgeons consider this discoloration as indicating disease of the bones; this is a mistake, for it may be observed in suppuration of the soft parts: and if it is more frequently produced by suppurations arising from the bones, it is because such suppurations are generally deep, and are seated in spots exposed to the atmosphere, and therefore are in conditions favourable to putrefaction and the formation of sulphuretted hydrogen. The formation of sulphuretted hydrogen, and its action upon the blood, suffice to explain a fact in pathological anatomy which I have often heard interpreted by a supposition of which I think I can prove the falsity. At the post-mortem inspection of large abscesses which have been opened during life, and particularly of those which proceed from caries, from tubercles of the vertebral column, or from the hip-joint, nothing is more common than to find the parietes of a very deep black colour. This colour is generally supposed to proceed from gangrene, while it is owing simply to the hydrosulphate of ammonia, and its action upon the blood. I have convinced myself by various experiments, that this

salt communicates a colour to the blood deeper than that of venous blood. Among these experiments I will quote the following one:—

I injected some blood which had been stirred in the air and deprived of its fibrine, into a knuckle of the small intestine; and when the parietes of the intestine had been strongly reddened by the blood, I macerated them partly in a solution of sulphuretted hydrogen and partly in a solution of hydrosulphate of ammonia: in both cases they became of a very deep black, just like the parietes of the abscesses which are supposed to be gangrenous. We may observe, too, that the discoloration of these abscesses depends so much on the action of sulphuretted hydrogen, that it is only found when it has been possible for sulphuretted hydrogen to be formed; and that it never has been found in abscesses which have not been opened—that is to say, in those which cannot contain putrefied pus; and that this tint does not seem to be formed until after death; for on post-mortem examination, it is often recognized before dissection, without having been perceived during life.

I shall terminate this article upon putrefied pus by the following observation. Even when pus blackens diachylon and the lead wash applied to the parts which furnish it—even when its vapour, without raising the temperature, communicates to re-agents all the colours which are produced by sulphuretted hydrogen—these same re-agents, poured into the pus, produce merely white precipitates; that is to say, the same which would result from their action on pure albumen: a new proof of the difficulty of recognizing the most characteristic substances, when they are mixed with albumen, and a proof, consequently, of the necessity of not examining them until they have been freed from this substance, which masks them so completely.

The force of pus, which I suppose to depend chemically upon the hydrosulphate of ammonia, with an excess of the alkali, may, without question, depend upon the putrefaction of pus, which is subject to all the conditions favourable to putrefaction when it is in a large abscess, in contact with the atmosphere, and surrounded by the natural heat of the human body: it is so certain that its putrefaction is the original cause of its force, that this force is never found in the pus obtained from unopened abscesses, and is peculiar to that which has been in contact with the atmosphere, the indispensable element of putrefaction. But when the hydrosulphate of ammonia comes in contact with the tissues of the body, it is absorbed and

carried into the blood, and exhaled by the urine*; but if the hydrosulphate of ammonia, which alters the state of the blood, tends to escape by the urine, it may do also by all the exhaling surfaces, and particularly by those which secrete pus. This makes me believe, that when the blood has been once affected by the absorption of hydrosulphate of ammonia, the pus found on the surface of solutions of continuity does not owe its force only to the putrefaction which it undergoes, but to its mixture with the putrid principles exhaled by these solutions of continuity, as they are by the kidneys. Perhaps, in such cases, the pus of unopened abscesses would show signs of decomposition; but however this may be, the original cause would be the local injury, the putrefaction of pus, and its contact with the atmosphere; which I hold it important to establish, to show the utility of the point which I aim at, in the practical application of my researches†.

[To be continued.]

ON MALIGNANT REMITTENT FEVER.

To the Editor of the Medical Gazette.

SIR,

THE inclosed remarks on the “malignant remittent fever” of the West Coast of Africa, drawn from personal observation, may perhaps be considered worthy of notice in your journal.

I am, sir,

Your obedient servant,

J. MACDIARMID.

High Row, Kensington Lane,
Nov. 16, 1837.

The colony of Sierra Leone has again been visited by one of those fearful outbreaks of disease which periodically threaten the very existence of the set-

* The second part of this memoir will contain the proofs deduced from chemical analysis.

† This is somewhat obscure, but we believe that the following is our author's meaning. He asserts that pus cannot putrefy unless the abscess is open; with this exception, however, that if, in consequence of the opening of an abscess, the pus has become putrid, its hydrosulphate of ammonia may be carried into the circulation, and then deposited in another and unopened abscess, rendering its pus putrid likewise; but even here, he says, the *point de départ*, or origin of its putrefaction, would be the opening of the first abscess.—*Translator.*

tlement, in as far as the European population is concerned.

The points of similarity between the fever of this and of former periods are great; but as some of their features differ essentially, the few remarks to be offered will bear more upon these as facts, than upon the far more interesting but equally intricate questions to which they naturally give rise. The combined causes (whatever they be) which produce such deleterious effects on the human frame, as have lately been witnessed on this coast, would appear to have been in operation early in the year, a decided case of "black vomit" having occurred on board a merchant vessel in one of the rivers, about the end of January—I believe the only one among several cases of fever from the same vessel in which that characteristic symptom appeared. At intervals from this period several suspicious cases were noticed, but the full development of the disease may perhaps be dated from one which occurred on the 16th April, and terminated fatally on the 19th, being followed by an almost uninterrupted series of cases, and, I regret to say, nearly as many deaths.

During May the cases were more frequent, and (if possible) in a more concentrated form; one member of a family after another became its victim, and neither age, sex, temperament, nor habits, appeared to influence it in the slightest degree. It was now, too, spreading along the coast, accounts reaching us from the southward that the men-of-war in that direction were suffering from its effects, at the same time that the merchant vessels from the northern rivers were sending in numbers of the most malignant cases. While the disease, however, was thus sweeping along the shores and neighbouring rivers, the mountain villages were altogether exempt, and the military station, too, in a remarkable degree, although in the immediate neighbourhood of the town. The barracks are elevated about 400 feet above the town, and enjoy an open and free circulation on all sides. Of the officers, the surgeon of the Royal African Corps was the only one attacked; and among the native soldiers only two cases appeared, both of them, however, terminating fatally.

Under these circumstances it may be supposed how anxiously a change was

looked for, and with what joy the first fall of rain was welcomed by those whom the experience of former years had taught its beneficial effects. I am happy to add, that the rains set in heavily towards the end of the month, and their expectations were in some measure realised by the beginning of June.

The disease which thus carried off, in a short period, upwards of one-third of the European residents of Freetown, independent of merchant seamen and others, was generally ushered in by the premonitory symptoms of common fever, occurring during the night in many cases, and described by the patient next morning, on sending for medical assistance, as "not having felt well on going to bed;" sleep absent, or disturbed by uncomfortable dreams, followed by headache, thirst, and restlessness; pains generally over the body, or (what is more characteristic of this particular fever, though not always present) a burning heat and oppression at the precordia. On examination, skin extremely hot and dry; eyes sometimes, even at this early stage, suffused; headache now intense, particularly over the orbits. Pulse 120 to 130, and sometimes strong, but generally weak; tongue dry, furred, and tremulous; pain in the abdominal region, particularly referable to the epigastrium; the headache and the last symptom varying in severity, and seldom present together in any marked degree, the pain in the abdomen being often absent entirely in some of the very worst cases, and those, too, in which the post-mortems displayed extensive patches of inflamed, ulcerated, and phagedenic intestine. Dyspnoea, more or less, an occasional symptom, with nausea, and vomiting of watery mucus, or diluted yellow bile; stools, when procured, copious, dark, and extremely fetid.

About the third day the disease will appear to yield to the treatment employed; headache either entirely gone, or reduced to a slight vertigo on sitting up; pulse moderate; very slight or no irritability of stomach; evacuations much improved in character, with a distinct bilious tinge, with either a tenacious salivary discharge from the mouth, or a decided tenderness of the gums. Amidst all this seeming success, however, some lurking symptom will betray itself to

the medical attendant, realizing in a short time his very worst fears. The case now retrogrades; the patient does not feel so well; had a wretched night; every symptom of salivation has disappeared; countenance and manner anxious. If not previously, eyes now suffused, and skin either of a peculiar dirty hue, or of a decidedly bilious tinge. Evacuations since last visit frequent, scanty, and harassing; appearance watery, dark, and without a trace of feculence, or suppressed altogether; considerable oppression in the breathing; sense of weight at the præcordia.

This state is speedily followed (in some cases in a few hours) by the closing scene; constant singultus, interrupted only by vomiting of coffee-ground matter; alvine evacuations (if any) of the same character, the peculiar factor of both impregnating the air of the whole room, and every article within it. Pulse scarcely to be felt at the wrist; action of the heart much oppressed; extremities cold and clammy, but no pain now complained of in any part of the body; mind clear, and painfully awake to the hopelessness of the case, even within a very short period of the fatal event.

This outline, as far as it goes, is characteristic of a number of the cases. The disease, however, in some ran on to a fatal termination, with only a very slight attack of fever at first, every irregularity of bowels, circulation, &c. being apparently corrected by the treatment employed, the patient continuing to declare, time after time, that no unpleasant symptom remained. In these cases a dry furred tongue, suffusion of the eyes, or the appearance of the skin already alluded to, gave you not only a mistrust of the case, but an almost certain assurance of danger, as too many melancholy instances tend to prove. A sudden oppression at the chest, followed by the "black vomit," are the first symptoms that succeed this treacherous calm, terminating in a state of collapse, miserably lengthened out to a period of many hours, during which, although all sensibility to external impressions appears gone, the audible and laborious respiration, together with the painful gestures of the body, and drawing up of the limbs towards the close, strongly impress you with the idea of intense suffering.

The exceptions to these general characteristics of the disease were cases proving fatal without the appearance of the "black vomit," three of which occurred under my care. There was also violent delirium in some few instances; and a degree of paralysis in two, with imbecility of mind, passing off in the one case, but terminating fatally in the other: the most remarkable exception being a case of recovery, in which the matter vomited, as well as the evacuations by stool, at one period of the disease resembled, and were in fact, the coffee-ground fluids noticed in fatal cases, the appearance of which has been so generally deemed the messenger of death. The patient was a married woman, young, and delicate in appearance, had been about two years in the colony, had suffered from the climate severely, and was the mother of one child at the time, about a twelvemonth old.

Up to the latter end of June, at which time the tornadoes were becoming frequent and heavy, and the fever consequently nearly extinct, the deaths were, to the whole population of Freetown (not including the military), in the proportion of one to three. The number of ladies resident in Freetown at the time was, I believe, nine; of these five were attacked, and three recovered, shewing a less mortality than in the other sex. Of European children there were not more, I think, than six; two of these had slight attacks, and none died. Of the losses of the several ships of war I am unable to speak; and of the merchant seamen I can only state, that the numbers under my care between the 16th May and 7th June were thirty-seven cases of fever, out of which there were eleven deaths.

The treatment of this formidable disease essentially consisted in procuring the constitutional effect of mercury, as soon as possible, relieving the local symptoms in the meantime, as far as the disease would permit, and keeping up a moderate but constant action on the bowels, so as to prevent any accumulation of the vitiated secretions. A scruple of calomel was generally administered at first, followed by the same preparation combined with opium, in the form of three-grain pills, to be taken every two or three hours; or should the scruple dose not have procured several copious stools, another

was ordered, combined with rhubarb (and ipecac., where no irritability of stomach was present,) divided into four powders, and administered every three hours. Leeches to the head, in large numbers, were resorted to, if necessary; and on the slightest uneasiness being complained of in the abdominal or sternal region, a blister, nearly covering the epigastrium, was applied; this was surrounded by five or six dozen of leeches, and the whole of the abdomen and lower part of the chest fomented with pieces of blanket wrung out of boiling water, and applied the moment the leeches were removed, continuing this latter for half an hour, and repeating it at longer or shorter intervals, according to the necessity of the case. Mercurial inunction was never omitted; and warm enemata, simple or laxative, according to circumstances, proved too useful and too grateful an auxiliary to be overlooked, even in the most promising cases, although, on the whole, no remedy afforded such temporary (and I would almost say) permanent relief, as the repeated fomentations. Their application, in many instances, has been speedily followed by some hours of refreshing sleep; in others, by the appearance of a salutary moisture on the surface, assisting the operation of the laxatives administered, and in no case failing, for the time at least, in alleviating the severe pain and oppression so often complained of in the chest and abdomen. The extract of colocynth, with calomel, in the form of pill, was occasionally found useful; and supposing it admissible, quinine, either alone, or combined with a small quantity of calomel, so as to keep up the mercurial action, was administered during the favourable progress of the case. The scruple of calomel, followed, if necessary, by a blister over the epigastrium, or a mustard cataplasm, generally allayed the irritability of the stomach, at least for the time; and the most agreeable as well as most useful drink, was found to be small and repeated draughts of soda in a state of effervescence. Wine, or other stimulants, except when ordered during the patient's recovery, were only employed to keep the vital spark from expiring, in the hope of nature's eventually rallying.

This hope, however, was only realized in one extraordinary instance, that of

the lady already alluded to, in whom the "black vomit" had appeared, followed by a state of collapse affording little prospect of recovery; the extremities had become cold and clammy, and the pulse was scarcely to be felt at the wrist, when warm fomentations to the bowels were ordered, with hot bricks to the feet, and wine in spoonful every fifteen minutes. Nature did rally, and the patient, four days afterwards, was able to be dressed and removed to another house, although the melancholy cause of her removal was her husband's death, from the same fever. Her recovery was again checked a few days afterwards, by another death in the family; yet, in less than a fortnight from the time, she was perfectly recovered—the only survivor in a little family circle of five.

The last remedy I have to mention is blood-letting; but as it is one which has been most sparingly employed on this occasion, and that little with the worst success, I would only say that I am averse to its use in European cases on the coast of Africa, notwithstanding the powerful arguments in its favour which the post-mortems display. My limited experience, however, does not, perhaps, authorise me to form an opinion, for only in three cases was the lancet used, as far as I am aware; in two by the colonial surgeon, and in one by myself. They promised well at first; but delirium came on in two, and a degree of paralysis in the third, and they all proved fatal.

The case I chose for the purpose was that of a young sailor of a healthy appearance, in the earliest stage of the disease, and with nothing apparently contraindicating its use. I accordingly opened a vein in the arm, and allowed the blood to flow till he expressed himself as greatly relieved of a distressing headache, which formed the principal feature in the case. The arm was then tied up, 16 oz. having been taken, and two buckets of water were suddenly thrown over the patient. He was then well dried and put to bed, thanking me for the great relief he had experienced. The next object was to produce the mercurial action on the system; but ere this could be accomplished, the case began to decline, and the symptoms I have already alluded to preceded his death, which took place on the 13th day—an unusually lengthened period,

the deaths generally occurring on the fourth, fifth, and sixth days.

The few post-mortems which time and opportunity permitted, bore the most marked evidence of inflammatory action, and that, too, of an intense degree, in the several cavities of the body, but more particularly and more generally in that of the abdomen. In one native case which I examined, there were large dark patches on the peritoneal surface of the stomach towards its cardiac extremity, the portions of lining membrane corresponding to these presenting an advanced stage of inflammation; traces of inflammation were found in the small intestines; and the stomach, gall, and urinary bladders, contained the dark coffee-ground fluids; that of the gall bladder presenting more the appearance and consistence of liquid tar; the lungs were in a state of sanguineous engorgement throughout, and deluged the table with blood on being cut into. The next native case presented the same traces of abdominal inflammation, but in a more striking degree; the ileum especially, on exposing its mucous surface, shewed one dark mass of vessels, intersected by gangrenous patches, and large excavated sloughing ulcers. The case was that of Christopher Lynch, native private. In a European case examined, which had proved fatal without any appearance of black vomit, that fluid was found in the stomach to the amount of a pint; and the same traces of active inflammation were apparent in that organ, as well as in other portions of the canal, especially in the ileum, as noticed in the two native cases.

Such, then, being the leading characters of the fever of this year, as derived from the personal observation of a large proportion of the cases which occurred, I would now subjoin extracts from the Medical Reports on those of 1823 and 1829, as given by the medical officers on the station, that by comparing them with the description I have ventured to give of the last epidemic, the points in which they differ may be the more easily contrasted.

Extracts from the Medical Report of the Epidemic of 1823, at Sierra Leone.

The fever made its appearance in the early part of the year.

This disease was generally ushered

in with pain in the loins and limbs, but more particularly in the calves of the legs; sometimes distressing pain in the head, and at others great uneasiness about the præcordia, with occasional vomiting and irritability of stomach; the tongue in general white and tremulous, in some cases red and clean, and in a few an ingrained blackness was perceptible, but perfectly different from that collection of sordes which form a characteristic of the typhus gravior, no symptoms of which were observable during any stage of the disease. There was no great degree of heat on the surface of the body, but on grasping the limbs or body firmly, a stinging heat, producing a very peculiar sensation, was communicated to the hand, which it retained for a considerable time. The pulse hurried, and sometimes feeble, but seldom indicating any considerable degree of inflammatory action. No remarkable appearance of the urine; the eyes were generally suffused, and in most cases there was considerable anxiety during the first stage of the disease. This train of symptoms generally lasted for the first thirty-eight or forty hours, by which time the aperient medicine which had been administered had freely operated; but in vain were healthy bilious evacuations sought for. The disease became now evidently manifest in the thin dark fluid which was passed downwards in considerable quantities, and rendered particularly characteristic by innumerable small floating flocculi, which had very much the appearance of the washed and broken-down fibres of the blood.

The patient felt much relieved about this period, and appeared unconscious of his danger; and this delusive state often gave sanguine hopes to the attendants. This calm was followed by a morbid torpidity, or sometimes by low delirium. This state continued until the fourth day, when the inevitable forerunner of a fatal termination, 'the black vomit,' made its appearance; at first in small quantities, and mixed with the ingesta, but afterwards in amazing volumes, and ejected from the stomach with a most extraordinary spasmodic force.

The fluid had the appearance of diluted and broken-down coagululum of blood, and frequently with portions of coagulated lymph, assuming very much the appearance of the inner coat

of the stomach; the fluid gave a dark stain to linen, not easily removed, and had a raw unpleasant odour so perfectly peculiar, that, on entering the chamber, the state of affairs became immediately manifest. In some cases a troublesome hiccup occurred, and in these the matter vomited was less abundant. The state of the patient's mind was most peculiar in the latter stage of the disease: the poor sufferer seemed unconscious of his hopeless state, and generally expressed himself as being much better, until, the vital flame gradually receding from the surface and extremities, dissolution took place; which in some cases was preceded by violent straining of the eye-lids, incoherent expression, or by some convulsive motions. Sometimes, prior to this, a dingy-yellow appearance took place on the body, particularly on the neck and chest.

The post-mortems showed an inflamed state of the villous coat of the intestinal canal, and patches of inflammation and disorganization of the coats of the small intestines; the whole lined with a glairy mucus, and the dark-coloured fluid which constitutes the black vomit.

Observed to be particularly prevalent on the sea-coast. One strange characteristic, however, presented itself—that females and children were entirely exempted from the disease.

The symptoms were not those of an active or ardent fever. In no case could the salivary glands be subjected to the mercurial influence. The only patients who escaped were those in whom early venesection was had recourse to: those cases, however, were very rare, and were more than equalled by the fatal cases under like circumstances and treatment.

Not a single one recovered after the black vomit made its appearance.

Extracts from the Medical Report of the Epidemic of 1829, at Sierra Leone.

The disease was generally ushered in with pain in the loins and limbs, but more particularly in the calves of the legs; very severe headache; the temperature was, in several cases, much diminished, with torpor of the circulating system. Tongue furred, generally ash-coloured; in several cases it was clean, or prematurely red, generally

moist, when thirst was complained of. Eyes watery and suffused; on the fourth or fifth day a dirty yellow suffusion of the surface made its appearance, attended in most cases with a distressing irritability of stomach. As the disease advanced the vomiting increased, and a large quantity of dark fluid, resembling decomposed venous blood, was ejected from the stomach. At this stage of the disease disposition to coma existed, and generally the patient replied that he had no complaint, and was very well; but this delusive appearance was a certain prelude to death.

In the post-mortems, skin of a high yellow; omentum very vascular, and the external surface of the stomach and intestines were highly inflamed. In some cases the colon was dark, and in one the ileum appeared to be in a state of sphacelus, and contained a dark fluid, which, when washed off, a clear transparent mucus appeared tenaciously adhering to the inner coat of the stomach and intestines. On this mucus being scraped off, the inner coat of the stomach appeared highly vascular and red, and the different portions of the intestines that were examined, all presented the same marks of inflammation. In some cases this mucus resembled false membrane, and was detached among the dark grumous contents of the stomach and intestines.

In several of the cases the colon was remarkably contracted in its whole extent. The liver was large, and of a mottled appearance on the surface, and much distended with blood, which rushed forth when that organ was cut into. Gall bladder generally empty; nothing remarkable in the spleen. Evident marks of great determination of blood to the brain existed; the sinuses were distended with congested blood, and the membranes in a high state of vascularity: about an ounce of serum was generally found in the ventricles. The structure of the brain unusually firm."

"Considering the nature of the disease to be essentially inflammatory," says Dr. Sweeny, "bleeding was practised in the first stage, either to the relief of the headache, or to deliquium. Calomel, mercurial inunction, blisters."

No case recovered unless free pyæmia was produced.

Does it not appear, then, from the

history of these successive periods, that while the locality remained the same, and the constitution of the atmosphere, with its barometrical and other changes, afforded nothing remarkable as differing from a former period, still some circumstances must have been in operation, on one occasion or another, to produce the modifications of the disease which have been observed. The disease certainly appeared, in every instance, early in the year, and gradually became milder as the rains fell; and during the last visitation, I could not but remark that cases rarely happened during the continuance of a strong sea-breeze, while, on the contrary, three and four cases have appeared in the day, during the prevalence of the land wind, or in calm weather; those who were ill at the time appearing sensibly to feel its deleterious influence. On this point, however, I would not speak confidently, although such was my impression and such the effect, whatever might have been the cause.

Between the fevers of 1823, 1829, and 1837, the following points are, I think, strikingly contrasted:—

In 1823, "there was no great degree of heat of body;" in 1837, the heat of the body, especially of the trunk, was intense.

In 1823, "females and children were exempt;" in 1837, the former suffered nearly in the same proportion as males, and children were not exempt.

In 1823, the symptoms were stated as not being those of "an active or ardent fever;" in 1837, I would be inclined to say that they were very much of the character of an acute and ardent fever, although the pulse did not generally indicate the very violent inflammatory action which must have been going on to produce the extensive ravages observed in the post mortems.

In 1823, it appears that "in no case could the salivary glands be subjected to the mercurial influence;" in 1837, decided salivation was procured in several cases.

In 1832, "the only patients who escaped were those in whom early V. S. was had recourse to;" in 1837, the three cases in which that remedy was employed proved fatal.

And lastly, in 1832, not a single case recovered after the appearance of the "black vomit;" in 1837, one case recovered after its appearance.

In 1829, again, "the temperature of the body, in several cases, was much diminished, with torpor of the circulating system." This corresponds somewhat with 1823; but in 1837, as stated already, the heat of the body was intense and the circulating system active.

In 1829, the vomiting does not appear to have been an early symptom, not coming on till the fourth or fifth day, or, in fact, till the approach of death: in 1837, on the contrary, vomiting was a very general, and always in such an early symptom often subdued, but returning towards the close with the appearance of the coffee-grounds.

The appearance of false membrane in the course of the canal was not noticed, I believe, in 1837; the opportunities of observation were, however, rare.

In conclusion it is stated, that in 1829 no case recovered unless free ptyalism was produced; while, in 1837, several cases recovered without the appearance of salivation, especially the case of recovery from the black vomit, in which there was no salivation.

ON THE ANATOMICAL STRUCTURE,

AND ON

SOME OF THE MORBID CONDITIONS,

OF THE

VALVES OF THE AORTA.

To the Editor of the Medical Gazette.

SIR,

THE perusal, in your journal, of Dr. Macleod's lectures on rheumatism, in which reference is made to some opinions of mine, induces me to trouble you with a few additional remarks upon the same subject.

In a lecture, reported in the *Medical Gazette*, (vol. xvi. pp. 56, &c.) it was stated by me that the wart-like appearances, seen upon the semilunar valves of the heart, after death, in rheumatic carditis, often form "a kind of double festoon on each valve, from the sesamoid body in the centre to either extremity of its margin, following a *natural line of division between the thinner and thicker portions of the valve.*"

The natural structure here referred to, which I believe to be constant, has re-

ceived but little notice from anatomists. Its relation, however, to a peculiar morbid condition of these valves, makes it worthy of a more particular description.

The cardiac valves consist of a loose duplicature of the delicate membrane that lines the heart; the *endocardium* of modern pathologists. Between its folds is received a thin prolongation of fibrous tissue from the tendinous rings surrounding or constituting the several orifices which are furnished with a valvular apparatus. In the semilunar valves this fibrous substance does not interpose itself between the entire space of the folded membrane. It reaches the free edge of each valve at three points only, namely, at the centre, where it forms the *corpus aurantii*, and at the two extremities. Between these points it stops short, and has a definite limit and outline—a scalloped edge—and so leaves two crescentic portions of the valve, formed merely by the doubled endocardium. In this manner arises the distinction alluded to in my lecture, between the *thinner* and *thicker* parts of the valve. The crescentic edges are thin and transparent; the remainder of the valve is more or less thick, firm, and opaque. This structure obtains in the semilunar valves on both sides of the heart, but it is much more conspicuous in some hearts than in others; and more so always in the valves of the aorta, than in those of the pulmonary artery.

It is along the line of union between the scalloped edge of the thicker portion, and the inner convex margin of the two thinner crescentic portions, that the minute *vegetations* (as they have been called) most commonly arrange themselves. Sometimes they follow that double festoon very exactly and completely; sometimes their continuity is broken, and they straggle a little from the line; but still the general tendency to adhere to it is obvious.

I regret that I neglected to procure accurate drawings of some of the more perfect specimens of this curious arrangement that have fallen under my notice. The festoon was quite regular and entire, and of a deep red colour, (stained so, apparently, by the blood,) upon the aortic valves of a young woman who died about a month ago in the hospital, of diseased heart, and who had suffered many attacks of acute rheumatism. *Figure 2* is engraved

from a sketch of these valves, made at the time by Mr. De Morgan.

FIG. 1.

FIG. 2.

Figure 1 represents the *natural* appearance of the valves, as seen in a well-marked example from another subject.

Dr. Budd informs me that he has lately met with a specimen in which the crescentic segments of membrane were wanting. The edge of each valve was formed by a mere string; while the space between this cord and its corresponding arc was open, as if it had been accurately cut out. This appears to have been an extreme degree of that eribriform or perforated condition of the same membranous portion of the valves, which is not very uncommon.

Dr. Hughes has recorded (in the 19th vol. of the *Med. Gaz.* pp. 222, &c.) two very interesting examples of rheumatic pericarditis, characterized by the temporary occurrence of what I have ventured to call the *to-and-fro* sound;

i. e. of a sound resulting from the alternate rubbing of the two surfaces of inflamed membrane against each other in the successive movements of the heart. I was naturally pleased to find that Dr. Hughes had been led by his own experience to the same conclusions with myself, respecting many of the phenomena of rheumatic carditis. On one point, however, he has misunderstood me. He supposes that I refer all the changes which take place in the valves in these cases, to the *smooth surface* of the membrane covering them.

Such, however, is not, nor has ever been, my opinion. I have always believed that this *rheumatic inflammation commences* in the *fibrous* tissues belonging to the heart; and that the "puckering," "stiffening," "increased thickness and opacity*" of the valves, are owing to deposition within their folds; upon or between their *attached* surfaces. In this matter, therefore, I have the satisfaction of agreeing with Dr. Hughes, and, as far as I know, with most other pathologists. But that the free or serous surface also undergoes inflammation, and throws out the products of inflammation, I infer from the fact that the inflamed valves are sometimes folded back, and *adherent*† to themselves or to the walls of the heart or aorta. Of this I have seen several instances.

Dr. Hughes intimates his belief that the granulations or wart-like excrescences are not *morbid growths* from the membrane. Such, also, is, and has long been, my own opinion; and it has been frequently expressed to the pupils in the wards of the Middlesex Hospital. The membrane being inflamed, I conceive that a portion of the fibrin of the blood in contact with it is precipitated upon its surface, and there adheres; just as the retarded blood coagulates and becomes fixed to the lining membrane of an inflamed artery or vein—as a consequence of the inflammation. That this is the true explanation of the origin of these beads of lymph, I was led to suspect by the result of some experiments which Dr. Hope was obliging enough to invite me to witness two or three summers ago in Kimmerton Street. The aortic valves of an ass had been held back by a wire passed into the

vessel, with the view of ascertaining the cause of certain sounds of the heart. The animal was previously rendered insensible by a narcotic poison, and the circulation was kept up—languidly, however, towards the last—by artificial respiration. Soon afterwards, the heart was removed from the body and examined; and little beads of soft lymph, small warty excrescences in fact, were found to have been already deposited on the valves that had been mechanically irritated by the wire.

Does not this fact suggest a practical caution? Is it not probable that bleeding *ad deliquium*, in cases of rheumatic carditis, may favour or determine the formation of these vegetations?

You did me the favour last year, of inserting in your journal the history of a case of carditis, in which I had had, for the first time, the opportunity of verifying, after the death of the patient, the conclusions I had drawn from the occurrence, and the cessation, of the *to-and-fro* sound, during his life. I have since met with a second striking confirmation of the correctness of those conclusions. If you should think it worth accepting, the case shall be transmitted in time for your next number.

I have the honour to remain,

Your obedient servant,
T. WATSON.

Henrietta Street, Cavendish Square,
Dec. 6, 1837.

ON THE
TREATMENT OF SIMPLE FRACTURES OF
THE LOWER EXTREMITIES

BY MEANS OF
PLASTER OF PARIS CASTS.

BY WM. SWEETING, Esq.
Surgeon, Bridport.

THE attention of the profession has of late been a good deal directed to the management of fractures of the extremities, and with the most praiseworthy industry surgeons have laboured to discover means whereby their patients may be saved a modicum of the ordinary pain attendant on fractured limbs, and be rendered as comfortable as is compatible with their situation. With this view Mr. Amesbury recommends his apparatus, which displays considerable ingenuity, and an anxiety for the well-being of the afflicted; this Mr. Radley denounces as cumbersome, and indeed re-

* See MED. GAZ. vol. xvi. p. 58.

† Ibid.

jects all and every kind of splint, and relying on the curative powers of nature, insists that nothing more is necessary than a soft pillow upon which the fractured limb may rest: the generality of practitioners, however, disregarding all extremes, continue to employ the splint and bandage originally recommended by Mr. Pott.

Without meaning to disparage the labours of others, I am of opinion that we are greatly indebted to Messrs. Bond and Gale, of Glastonbury, in Somersetshire, for their valuable communication on the use of plaster of Paris cast, as a substitute for the common splint and bandage in fractures of the lower extremities. Although the employment of this material is confessedly no new discovery, the plan has been certainly lost sight of, or brought into disrepute, in consequence of some badly managed cases. Men are necessarily cautious in adopting any, to them, new course, and wait for the sanction of time, and the testimony of persons of acknowledged reputation, before they venture out of a beaten tract. Knowing Mr. Bond, independently of his professional acquirements, to be a very ingenious man, I felt no difficulty in adopting his suggestion with the regard to the treatment of fractures of the lower extremities by plaster of Paris casts, and within the last two years have had repeated opportunities of employing it, and with a success I could hardly have anticipated.

My object in reporting these cases is to lay before my professional brethren the result of my own experience, and to invite others to make trial of the plan, which I cannot help persuading myself will be, at no distant day, very generally adopted.

The first case in which I was led to employ the plaster cast was that of a man in the neighbourhood, about 40 years of age, named Orchard, over whose legs a loaded cart had been driven, fracturing both very severely: the right suffered a simple, the left a compound fracture. The tibia of the right leg was fractured into three distinct parts; a portion just below the tuberosity, of about three inches in length, being completely detached. My friend, Mr. Southcomb, of this town, was called to the case: the limbs were put up in the usual way, and every attention paid to the man; yet all his contrivances failed, and Mr. Southcomb was daily annoyed at finding the

detached portion of the tibia of the right leg displaced and riding over the others, which its wedge-like form facilitated. In this state of things my assistance was requested, and as it appeared to me to be a case to which the plaster cast would be peculiarly applicable, it was determined to try it: the limb was placed in a double-inclined plane, in a kind of trough, enveloped in the plaster, and thus properly secured: in this apparatus it was retained for five or six weeks, at the end of which the plaster was removed, and the limb found straight and well shaped.
